No significant difference in the fall of plasma volume could be demonstrated between the two

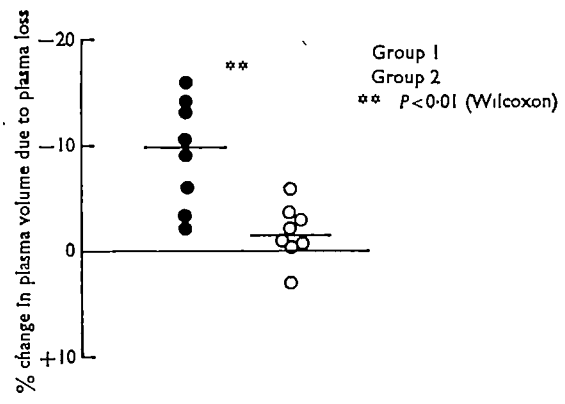

Fig. 9. Both subgroups are compared immediately postoperatively in relation to the loss of plasma as estimated by the differences between the plasma volume change as estimated by haematocrit and that by plasma protein concentrations.

groups (*Fig.* 7). A comparison of the change in volume of the space occupied by the preoperative marker ^{125}I (RISA) in the two groups did show a significant difference (*Fig.* 7). Group 1 showed the larger increase, i.e. this marker must have been diluted more in this group. Estimations of the volumes of intravenous fluids given to the group 1 patients showed significant differences (median group 1, 3·5 per cent ECF; group 2, 2·0 per cent ECF; $P<0{\cdot}05$). These findings are therefore a representation of the differences in intravenous administration.

If the contraction of plasma volume as measured by the preoperative (^{125}I) and postoperative (^{131}I) markers is considered in conjuction with the apparent rise in volume after operation as measured by the preoperative marker (^{125}I), thus nullifying the effect of the differences in intravenous administration, then there is a highly significant difference between the intra- and extra-abdominal groups (*Fig.* 8). This is also shown by the differences in the haematocrit and plasma protein concentration measurements (*Fig.* 9).

Discussion

The hypothesis that changes in plasma and extracellular volumes can be determined by measurement of haematocrit and plasma protein concentration has been discussed elsewhere (LeQuesne et al., 1960; Robarts et al., 1979).

A personal analysis of studies from the literature on patients known to have lost extracellular fluid shows close correlations between the changes in plasma volume calculated by the two methods—notably in cholera (Watten et al., 1959) and changes in posture (Eisenberg, 1963). The present studies on patients with simple intestinal obstruction, and during dumping provocation tests, confirm these findings and provide strong evidence for the validity of the hypothesis.

Previous studies have concentrated on showing apparent changes in extracellular fluid volume (ECFV) over the perioperative period. Before 1961, investigations showed an expansion of the ECFV (Stewart and Rourke, 1938; Lyon et al., 1949; De Cosse et al., 1956). In 1961 a large extracellular deficit was demonstrated postoperatively by Shires et al., and other workers produced similar results (Boba, 1966; Hoye, 1966). This led to the practice of giving large volumes of balanced salt solutions during operation. Since then these results have been criticized over the interpretation of the changing equilibration times of the marker isotope (^{35}S sulphate) used to measure ECFV (Cleland et al., 1966; Roth et al., 1969). These workers showed no difference between the ECFV before and after operation.

All these studies using dilution indicators must be criticized on the grounds that it is impossible to determine the space that any of them is entering. By measuring ratios of intrinsic components of the various compartments this criticism has been overcome, and the present studies clearly show that patients having abdominal surgery become significantly hypovolaemic following surgery and that this is brought about by a loss of plasma rather than by any overall change in the remainder of the ECF.

Where has the lost plasma gone? It has been noted before that the amount of protein which can be removed from the peritoneal cavity during abdominal surgery is greater than would be expected from the measurement of blood loss (Jarnum, 1961; Kragelund, 1971). However, these changes have not been equated with any fall in plasma volume. Hoye et al. (1972) did show large falls in plasma volume as measured by ^{125}I (RISA) but he also showed large falls in the whole extracellular volume as well, and recommended replacement with large volumes of balanced salt solutions.

The criticism that alterations in red cell mass might alter the significance of haematocrit changes could only be valid if there were a differential rise in red cell mass in the abdominal group. This did not happen, and there is no significant difference between the minimal losses measured by weighing swabs and losses calculated from the actual changes in total red cell mass. Other workers have noted similar results using ^{51}Cr-labelled red cells (Shires et al., 1961; Hoye et al., 1972).

The inability to show significant falls in plasma volume using RISA as a dilution indicator emphasizes the problems of interpretation of this technique, especially where the changes are relatively small and are masked by the effects of giving intravenous fluids. Only by combining the results of the plasma volume fall, as measured by ^{125}I (RISA) before operation and ^{131}I (RISA) after operation, with the apparent increase in the volume of ^{125}I (RISA) space due to intravenous administration, was it possible to show significant differences between the two groups. Nevertheless, a combination of these findings and the changes in haematocrit and plasma protein concentration strengthens the conclusion that there has been a significant loss of plasma in the group of patients undergoing abdominal surgery.

A lung colony clonogenic cell assay for human malignant melanoma in immune-suppressed mice and its use to determine chemosensitivity, radiosensitivity and the relationship between tumour size and response to therapy

J. MEIRION THOMAS*

SUMMARY

A lung colony assay for clonogenic cells of human tumours in immune-suppressed mice is presented. The assay was used to determine the chemosensitivity of two malignant melanomas. One tumour reproduced the spectrum of chemosensitivity associated clinically with three cytotoxic agents. The other melanoma reproduced the chemosensitivity demonstrated in the patient from whom the tumour was biopsied.

The importance of tumour size as a determinant of response to melphalan was investigated and the clonogenic cell survival in smaller tumours was found to be slightly but significantly lower than in larger tumours.

An investigation of the importance of size as a determinant of response to radiotherapy demonstrated that 0·5-mm diameter tumour nodules were significantly more sensitive to irradiation than 2-cm diameter nodules. The hypoxic fraction of the larger tumours was 65 per cent, which is higher than that reported for experimental animal tumours or a human pancreatic tumour. This could be a factor in the clinical radioresistance of malignant melanoma.

MAJOR advances in cancer chemotherapy will depend either on the development of better cytotoxic drugs or on the more efficient use of existing drugs. The development of laboratory methods for predicting the chemosensitivity of human tumours may lead to better selection of cytotoxic drugs and improvements in chemotherapy protocols.

Human tumours can be grown in laboratory animals either at immunologically privileged sites (Bradford Patterson, 1968), in nude (athymic) mice (Shimosato et al., 1976) or in artificially immune-suppressed mice (Castro, 1972). The response of tumours to cytotoxic agents is frequently assessed by monitoring volume change after treatment, but this method has been shown to be less sensitive than the assessment of clonogenic cell survival (Hermens and Barendsen, 1969). Cytotoxic agents preferentially kill proliferating cells, and because most tumour cells are non-proliferating, significant stem cell kill may have occurred with little or no change in tumour volume.

Two *in vitro* clonogenic cell assays have previously been described for human tumours (Smith et al., 1976; Courtenay and Mills, 1978), and this paper describes the first *in vivo* assay. The development of the *in vivo* lung colony assay has been made possible by a recent improvement in the method of immune suppression of CBA/lac mice (Steel et al., 1978; derived from the work of Millar, 1976). (A clonogenic cell is defined as a stem cell which on extraction from a tumour to a test environment retains the ability to produce a large family of descendants.)

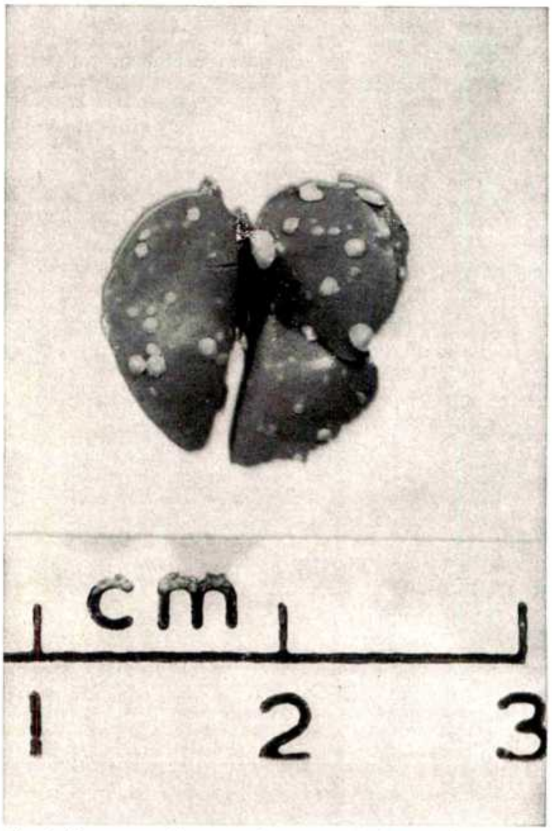

Fig. 1. Human malignant melanoma colonies on the lung surface of CBA mice.

Materials and methods

Male CBA/lac mice were immune suppressed by thymectomy and pretreatment with cytosine arabinocide (Ara-C) (200 mg/kg) 48 h before 900 rad total body irradiation.

It was observed that the i.v. injection of a single cell suspension of human malignant melanoma cells resulted in lung surface colonies (*Fig.* 1), and that there was a linear relationship between the number of cells injected and the number of lung surface colonies produced.

The lung colony assay

The assay (*Fig.* 2) was developed using two human malignant melanoma xenografts (laboratory designation HX34 and HX46). HX34 was obtained by biopsy of a metastatic cervical

lymph node and HX46 from a subcutaneous metastasis of malignant melanoma.

The tumours were grown subcutaneously in Ara-C-prepared mice and passaged every 3–4 weeks. Disaggregation was performed by finely chopping the tumour into tiny pieces under sterile conditions by the crossed scalpel technique. Culture medium (Ham's F12 with 15 per cent Special Bobby Calf Serum from Gibco-Biocult) was added to the homogenate and the suspended pieces pipetted into a sterile capped Falcon tube. The tube was shaken violently to dislodge cells and the cell suspension was removed by pipette and filtered through a sheet of polyester mesh (pore size 30 µm, Henry Simon, Stockport). The single cell suspension thus obtained was centrifuged so that a small pellet of cells lay at the bottom of the Falcon tube. The supernatant containing the debris was decanted away and the pellet of cells suspended in culture medium. Viability of cells was assessed by dye exclusion using Lissamine Green, and viable cells were counted on a haemocytometer. A known number of cells was injected into mice via the tail veins and after a growth period of 24–30 days the mice were killed by cervical dislocation and the lungs removed and fixed in Bouin's fixative for 48 h. The lobes of each lung were then dissected apart and the lung surface colonies counted by dissecting

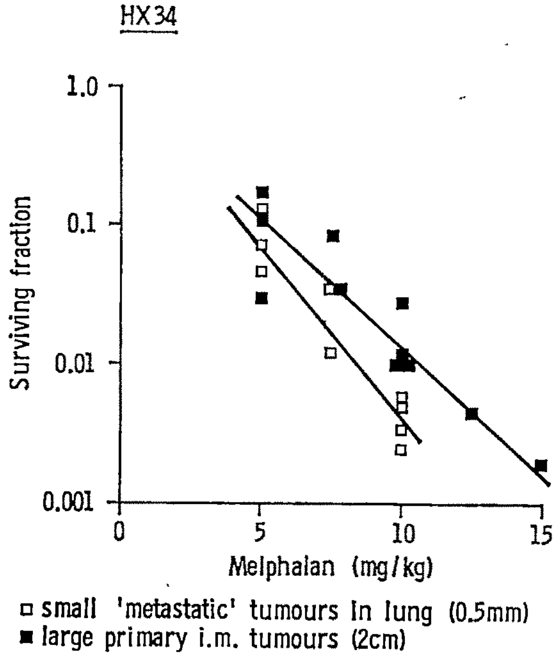

Fig. 7. Clonogenic cell survival curves for large intramuscular primary tumours (2 cm diameter) and small 'metastatic' tumours in the lung (0·5 mm diameter) following treatment with melphalan.

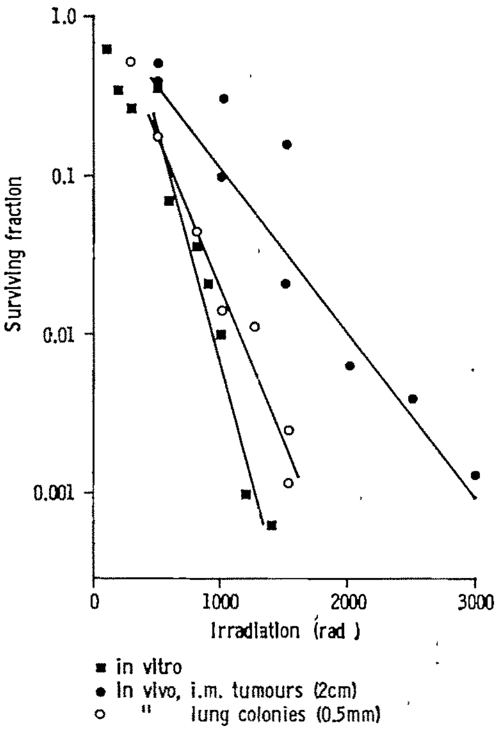

Fig. 8. Clonogenic cell survival curves of *in vivo* irradiated single cell suspension, *in vivo* irradiated intramuscular tumour (2 cm) and *in vivo* irradiated lung colonies (0·5 mm) (HX34).

microscope. The cloning efficiency (number of lung surface colonies divided by number of viable cells injected) for HX34 varied from 0·2 to 1 per cent and that of HX46 from 0·05 to 0·1 per cent.

The time at which colonies were scored following i.v. injection of viable cells varied with the growth rate of the tumours and was determined by time-course study (*Fig*. 3). The number of lung surface colonies at various times following injection of viable cells was determined and for HX34 there was evidence for a 'plateau' beyond approximately the twenty-first day. For HX46, a more slowly growing tumour, the 'plateau' was not reached until approximately the thirtieth day. An incubation period on the steep mid-portion of the curve was avoided and the exact day on the 'plateau' for terminating the assay was decided after colony size distribution studies (*Fig*. 4). For HX34 and HX46 these showed that at 24 and 30 days respectively there was a narrow distribution of colonies around a mode of 0·6 mm, which was a convenient diameter for counting by dissecting microscope.

Attempts were made to enhance cloning efficiency of viable cells by admixture of 10^6 plastic microspheres (15 μm, 3M Co. Ltd) or 10^6 lethally irradiated cells as described for experimental animal tumours (Hill and Bush, 1969; Hill and Stanley, 1975). The cloning efficiency was in fact reduced to one-third by either manoeuvre (Mann–Whitney, $P = 0{\cdot}014$; $P < 0{\cdot}002$ respectively) and was therefore not employed.

Chemosensitivity testing

Mice bearing subcutaneous or intramuscular tumours 1 cm in diameter were selected for study and the cytotoxic agent (Adriamycin, melphalan or MeCCNU (methyl 1,2-chloroethyl-3-cyclohexyl-1-nitrosourea)) was injected 18 h before assay in doses up to the LD_{10} (the dose lethal to 10 per cent of mice). In male CBA/lac mice of the Institute of Cancer Research colony the LD_{10} for Adriamycin and melphalan was about 15 mg/kg and for MeCCNU about 30 mg/kg. Control animals were included with each experiment. At least 6 mice were used for assay at each test point and the mean lung colony count at that test point determined. The cloning efficiency (CE) for control and test tumours was calculated:

$$\mathrm{CE}=\frac{\text{Mean colony count/lung}}{\text{No. viable cells injected i.v.}}$$

The surviving fraction (SF) of clonogenic cells following treatment by the test agent was calculated:

$$\mathrm{SF}=\frac{\text{CE test}}{\text{CE control}}$$

Initially a pilot experiment was performed at only one dose level but with a range of treated viable cell numbers. In this way, the approximate survival curve was derived. With this information a larger experiment was prepared with several dose levels, and the single cell suspension obtained from each of these diluted or concentrated as necessary to a final concentration that would provide an estimated countable number of lung colonies at each dose level. The greater the estimated cell kill, the larger the numbers of viable cells injected.

The data for clonogenic cell survival after treatment of HX34 (*Fig.* 5) were fitted with straight lines by linear regression analysis using the method of least squares and a computer program made available by Dr J. Millar. The lines were not constrained to go through the origin. The D_{10} (dose of drug required to achieve 1 log tumour cell kill) for Adriamycin (37·7 mg/kg) was significantly different ($P<0·01$) from that for melphalan (5·5 mg/kg) which was significantly different ($P<0·01$) from that for MeCCNU (4·25 mg/kg).

The data for treatment of HX34 and HX46 with MeCCNU (*Fig.* 6) show that the slope for HX34 ($D_{10}=4·25$ mg/kg) was significantly different ($P<0·01$) from that for HX46 ($D_{10}=59·5$ mg/kg).

Tumour size and response to chemotherapy

Cell survival in 2-cm diameter subcutaneous tumours and 0·5-mm diameter lung colonies (HX34) was compared following treatment with melphalan. Mice bearing lung colonies of 0·5 mm in diameter were prepared 3 weeks before assay by injecting sufficient viable cells to produce about 200 colonies. The mice were injected with intraperitoneal melphalan and, 18 h later, killed, and a single cell suspension of the lung colonies performed by finely chopping whole lungs and proceeding as previously described (*Fig.* 2).

The survival curves are illustrated in *Fig.* 7 and the slope of the survival curve for large i.m. tumours ($D_{10}=5·51$ mg/kg) is significantly different ($P<0·01$) from that for small lung colonies ($D_{10}=4·16$ mg/kg).

Tumour size and response to radiotherapy

Similarly, the clonogenic cell survival of 2-cm diameter subcutaneous tumours and 0·5-mm diameter lung colonies (HX34) was compared following single fraction irradiation (*in vivo*). Total body irradiation was used and no shielding of bone-marrow or gut was necessary as the animals were killed 18 h later for assay (*Fig.* 8).

Tumour cells are maximally radiosensitive when irradiated as a single cell suspension under fully oxygenated conditions and an *in vitro* survival curve was derived by irradiating a single cell suspension of HX34 prepared from untreated tumours (*Fig.* 8).

The slope of the exponential portion of the irradiation survival curve is expressed as that dose of irradiation (D_0) required to reduce survival to e^{-1} (37 per cent). The D_0 for *in vitro* irradiation was 144 rad; for *in vivo* irradiation of 0·5-mm lung colonies 220 rad and for 2-cm subcutaneous tumours 417 rad. The slopes of the three survival curves are statistically different ($0·01<P<0·05$).

The hypoxic fraction of the 2-cm diameter tumours was calculated to be 65 per cent on a multi-target equation assuming a mixed population of oxygenated and hypoxic cells in which the oxygenated cells were assumed to have the D_0 and n (extrapolation number) value of the lung colony survival curve and the hypoxic cells to have the D_0 of the 2-cm subcutaneous tumour.

Discussion

The lung colony assay for human malignant melanoma in immune-suppressed mice can be used to quantitate human tumour cell kill and may be useful in predicting clinical chemosensitivity. One melanoma (HX34) demonstrated a spectrum of chemosensitivity to three cytotoxic agents which broadly parallels the clinical experience with the same drugs in the treatment of disseminated melanoma. Adriamycin is regarded as having little activity while MeCCNU is considered to be one of the most effective agents in this situation. However, minimal tumour cell kill was achieved when HX46 was treated with MeCCNU, and it is interesting to note that the patient from whom HX46 was biopsied was treated with CCNU with no objective evidence of remission of disease.

A popular concept in cancer chemotherapy is that smaller tumours are more sensitive to chemotherapy (Frei, 1966; Schabel, 1975), and this concept has exerted an important influence on the design of some protocols of maintenance and adjuvant chemotherapy. The 'small is sensitive' theory is derived from the results of investigations on rodent tumours whose growth kinetics are greatly different from those of human tumours. Cytotoxic agents act mainly on proliferating cells and smaller rodent tumours with a better blood supply are more sensitive because of their higher growth fraction, shorter mean cell cycle time and better drug penetration. In the present investigation on a human melanoma, smaller tumours were again more sensitive but the difference in slopes of the survival curves was small. This finding is supported by the lack of clinical evidence of size-sensitivity to chemotherapy. If size is not an important determinant of response to chemotherapy, then it follows that chemotherapy may be most effective when tumour bulk is least and that adjuvant chemotherapy should be prescribed in maximum tolerated dose. Following the disappointing results of low-dose, short-course adjuvant chemotherapy, several trials have now been published where significant prolongation of the disease-free interval has followed intensive adjuvant chemotherapy (Bonadonna et al., 1976; Eilber et al., 1978; Pratt et al., 1978).

The importance of tumour size as a determinant of response to radiotherapy has long been recognized. It is likely that small tumour deposits are well vascularized, fully oxygenated and therefore relatively radiosensitive while large deposits have hypoxic cells associated with areas of necrosis and consequent reduced radiosensitivity. In the present study, a human melanoma 2 cm in diameter was shown to have a hypoxic fraction of about 65 per cent, which is greater than that reported for experimental animal tumours (Rockwell and Kallman, 1973; Shipley et al., 1975) or for a human pancreatic tumour (Courtenay et al., 1976). However, the slope of the *in vitro* survival curve was similar to that previously reported for *in vitro* irradiation of single cell suspensions of rodent tumours (Hill and Bush, 1969; Thompson and Rauth, 1974) and human tumours (Barranco et al., 1971; Thompson et al., 1975). This similarity of *in vitro* D_0 values for human and animal malignant cells supports the view that the main determinant of radiosensitivity or radioresistance is hypoxia in the *in vivo* environment. The clinical radioresistance of human malignant melanoma correlates well with the very large hypoxic fraction demonstrated in this study.

Acknowledgements

I am grateful for the support and encouragement of Dr G. G. Steel, Professor M. J. Peckham and Mr J.-C. Gazet during this research work. Technical assistance with counting of lung colonies was provided by Miss Kay Adams. Mr T. Merryweather prepared and maintained the immune-suppressed mice. I am very grateful to Dr John Miller for help with statistical analysis. I am grateful to Miss Lynn Baxter for patiently typing the manuscript.

I am grateful to Mr J.-C. Gazet for sponsoring this work for the Moynihan Prize.

Statistical note

The cell survival curve for mammalian cells described was derived by Lea (1946) and is given by:

$$SF = 1-(1-e^{-D/D_0})^n,$$

where SF is the surviving fraction, D is the dose to give this survival, D_0 is the negative reciprocal of slope on the exponential part of the curve on a semi-log plot and n is the extrapolation number.

To simplify calculations, this approximates to:

$$\log_e SF = \log_e n - D/D_0 \quad (\text{if } D > D_0)$$

and this latter formula was used here to calculate the values of slope, intercept and the errors on these by linear regression analysis as formulated in *Geigy Scientific Tables* (1970). The regression of $\log_e$ SF on dose D has been calculated by the method of least squares. This is to say that a straight line was established such that the sum of the squares of the vertical deviations of the given points from this line was a minimum.

Comparison of slopes for statistical significance

An F test (variance–ratio test) was done to see if the variances about both regression lines were similar. If so, a t value was calculated and the probability P obtained from tables (Bailey, 1959). If the variances were significantly different a d value was calculated as suggested by Bailey (1959) and again P obtained from tables.

The interpretation of mammographic ductal enlargement in cancerous breasts

R. E. MANSEL, I. H. GRAVELLE AND L. E. HUGHES*

SUMMARY

The xeromammograms of 128 women with breast cancer were coded radiologically according to Wolfe's gradings. The mastectomy specimens were then histologically examined for the presence of ductal abnormality.

The ducts were found to be normal in the cases coded as normal radiologically but they were not always abnormal histologically when considered to be abnormal radiologically. 'Ductal prominence' may be due to duct ectasia, intraduct hyperplasia or periductal collagenosis.

IF the best results are to be achieved in surgery for potentially curable breast cancer, early diagnosis is mandatory. A marker which either precedes the onset of invasive breast cancer or is detectable in high risk cases would allow very early diagnosis. According to Wolfe (1967, 1976) duct thickening visible on mammography is such a marker and women with prominent ducts or dense breasts on radiography have a higher risk of developing future breast cancer. Wolfe states that the increased radiodensity of prominent ducts is due to a periductal collagenosis, based on a study correlating radiology with pathology of excision biopsy specimens (Wellings and Wolfe, 1978).

A formal prospective study directed primarily at the subareolar ducts is needed since there are other possible causes of increased ductal density on mammography, such as duct ectasia. As it is not possible to obtain histological material on the whole group of patients with radiologically dense breasts, we have studied a consecutive group of cancer patients (with and without radiological duct abnormality) undergoing mastectomy.

Patients and methods

One hundred and twenty-eight consecutive unselected mastectomy specimens were examined radiologically and pathologically. The radiological examination consisted of routine preoperative xeromammography using the Rank Xerox System 125 taking xeromammograms in the craniocaudal and mediolateral planes (Gravelle and Hallett, 1975). The xeromammograms were read and classified on Wolfe's criteria by one radiologist (I. H. G.) without prior knowledge of the pathological results. Breasts with invisible ducts and little density were classified as N1 (normal); breasts with few visible ducts as P1 (minimal prominent duct pattern); those with many visible ducts as P2 (severe prominent duct pattern) (*Fig.* 1); and those breasts with generally increased density which obscured the underlying ductal pattern as DY (dense parenchyma/dysplasia pattern) (*Fig.* 2).

The pathological examination was carried out by sectioning the mastectomy specimens after the pathologist had taken his diagnostic blocks. The breasts were sliced to produce cross-sections of the subareolar ducts and sections for light microscopy were taken at three depths—0·5, 2 and 3 cm measured from the base of the nipple. These sections were stained with haematoxylin and eosin and examined by one of the authors (R. E. M.) who was unaware of the radiological classification at that time. The internal diameters of any ducts present were measured by using a calibrated eyepiece scale and the presence or absence of periductal collagenosis and intraductal hyperplasia were recorded. An internal ductal diameter exceeding 1 mm was selected to define the presence of duct ectasia.

Results

The numbers of mammograms in each of the four radiological subgroups are shown in *Table I*. As would be expected amongst cancer patients, few mammograms were classified as N1 and the commonest group was the severe prominent duct pattern or P2, which formed 53 per cent of the total. The incidence of periductal collagenosis and ductal dilatation in each radiological group is shown in *Table II*. Dilated ducts were not seen in the N1 breasts but were present in 32 per cent of P1 breasts, 33 per cent of P2 breasts and 39 per cent of DY breasts. Collagenosis was also absent in the N1 breasts but was found in 40 per cent of P1 breasts and in 53 per cent of P2 and DY breasts (some of these patients had both collagenosis and dilated ducts). Thus, approximately half of the breasts that showed increased ductal density radiologically were not found to have collagenosis of the subareolar ducts on histological examination. *Table III* gives the pathological findings in the 'no collagenosis' subgroup. Of the 15 such cases in the P1 group, 8 were shown to have either duct ectasia or intraduct hyperplasia which could explain the increased radiodensity, but in 7 breasts no histological cause for increased radiodensity could be found, thus giving a false positive radiological rate for the group as a whole of 28 per cent. Similarly the false positive rates for the P2 and DY groups were 13 and 11 per cent respectively.

Discussion

This study has shown that collagenosis is not invariably the cause of the prominent duct patterns in mammography. While the ducts are found to be normal when the radiologist reports them as such on mammography, they are not always abnormal histologically when they are considered to be abnormal by Wolfe's criteria. It seems clear from this study that duct ectasia and intraduct hyperplasia may cause the prominent duct pattern in a considerable percentage of cases. In a further small group (28 per cent in P1 and 13 per cent in P2) there is no obvious abnormality found on histological examination. The false positive rate amongst P1 cases is not altogether surprising, since it is not easy to separate the normal and P1 groups. However, the absence of histological abnormality in the P2 group is more difficult to explain. It is possible that in some cases the radiologically prominent ducts lie deeper in the breast than the subareolar region which we have studied histologically, and we are planning further studies of the whole breast to resolve this question. A further possibility is that in a number of cases the radiological appearance is primarily due to lobular abnormalities, as suggested by Wellings and Wolfe (1978).

	9 Normal	(False positive rate 9/69 = 13%)
DY ($n = 13$)	5 Ectatic	
	5 Hyperplastic	
	3 Normal	(False positive rate 3/28 = 11%)

The significance of histological collagenosis in relation to breast cancer is still in dispute, although it is accepted that there is frequently an association. Jackson and Orr (1957) reported finding a 70 per cent incidence of collagenosis in a detailed study of cancerous breasts and concluded that this feature in the presence of epithelial atypia should be regarded as pre-malignant. In contrast, Davies (1972), in a large study of both 'normal' post-mortem and cancerous breasts, found that the incidence of ductal hyperelastosis, obliteration and fibrous plaques was similar in both types of breast.

At the present time Wolfe's hypothesis of increased cancer risk associated with radiological duct abnormality is the subject of controversy. There are reports both substantiating (Krook, 1978) and disputing (Mendell et al., 1977) Wolfe's views. Direct correlation of pathological and radiological changes as reported here should lead to a greater appreciation of the spectrum of conditions which give rise to abnormal radiological findings. Hopefully this may lead to recognition of more specific radiological patterns, allowing better evaluation of Wolfe's hypothesis and better prediction of cancer risk.

The value of measuring intravascular platelet aggregates in the prediction of postoperative pulmonary dysfunction

C. N. MCCOLLUM AND I. T. CAMPBELL*

SUMMARY

A modified Swank screen filter technique was used to investigate, first, whether intravascular platelet aggregates (IPA) could be detected in patients immediately after surgery and then, the relationship between IPA levels and postoperative pulmonary function. The test, as modified, achieved an excellent reproducibility ($r = 0{\cdot}95$) and a close correlation with the number of aggregates identified in samples of femoral vein blood by subsequent scanning electron microscopy ($r = 0{\cdot}93$).

In 20 patients IPA levels were measured 30 min and 3 h after surgery and pulmonary function (arterial Po_2, physiological dead space and alveolar/arterial Po_2 gradient) was evaluated preoperatively and on days 1 and 7 postoperatively. Patients with elevated IPA levels suffered a greater mean fall in arterial Po_2 at 7 days (1·8 kPa) than did patients with normal IPA levels (0·6 kPa) ($P < 0{\cdot}05$). This was explained by a marked increase in the pulmonary arteriovenous shunt as indicated by the alveolar/arterial Po_2 gradient (2·3 kPa v. 0·4 kPa, $P < 0{\cdot}01$). Those patients with increased pulmonary shunting and arterial hypoxia 1 week after surgery also had a greater fall in the platelet count on the first postoperative day.

The screen filtration technique is a reproducible test which measures IPA accurately and may be used to predict pulmonary function 1 week later. This suggests that treatment to inhibit IPA may reduce postoperative pulmonary dysfunction.

POSTOPERATIVE hypoxaemia is a well-recognized complication of surgery. In the immediate postoperative period it has been ascribed to the depressant effects of anaesthetics and analgesics, to pulmonary atelectasis, to inadequacies of blood volume and cardiac output in relation to tissue oxygen demand and to the effect of anaesthesia and postoperative pain on functional residual capacity in relation to closing volume (Bendixen et al., 1963; Kelman et al., 1967; Spence and Alexander, 1972). However, poor arterial oxygenation which continues beyond the immediate postoperative period, when these factors have ceased to apply, has not been adequately explained. This persistent hypoxaemia has many of the features of the condition known as post-traumatic pulmonary insufficiency or 'shock lung'; in both instances patients are hypoxaemic with normal or low arterial carbon dioxide tensions (Moore et al., 1969). McNamara et al. (1970) demonstrated, in battle casualties, a crude correlation between the severity of hypoxaemia and the volume of blood transfused. This was attributed to pulmonary sequestration of particulate matter in the transfusion with subsequent damage to the lung tissue. It has been suggested that, even without blood transfusion, a similar process may occur in shocked patients as a result of spontaneous platelet aggregation (Pardy and Dudley, 1977). However, as no method has yet been shown to measure circulating microaggregates *in vivo* reliably, their role in the development of pulmonary damage remains speculative.

Swank (1961) described the technique of screen filtration pressure (SFP) for the measurement of particulate matter in stored blood. We have modified and evaluated this technique as a means of measuring intravascular platelet aggregates (IPA) in postoperative patients. The relationship between these aggregates and pulmonary function following elective major surgery was then investigated.

Patients and methods

SFP technique

The screen filtration pressure technique (Swank et al., 1964) was modified to measure *in vivo* aggregates (*Fig.* 1). A nickel filter of 2·4-mm diameter and pore size 20 μm square and deep was primed by the passage of 5 ml of normal saline at 37 °C. The 5-ml test sample of blood was aspirated by femoral venepuncture into a plastic syringe and passed through the filter by a syringe pump at a constant flow rate of 0·4 ml/s. The pressure proximal to the filter was measured by a strain gauge transducer and recorded graphically as the SFP test curve. No anticoagulants were added and any sample which had not completed the test within 45 s of venepuncture was discarded. The filter was finally flushed with a further sample of saline and preserved in buffered 0·5 per cent gluteraldehyde prior to examination by scanning electron microscopy (SEM).

A scanning electron photomicrograph of the filter area was taken at a magnification of × 200. From this a count was made of the total number of pores completely obscured by aggregates, the maximum number of pores per field at this magnification being 140. These SEM counts were compared with various parameters such as the height and slope of the SFP curves.

SFP evaluation

The SFP recordings were performed within 30 min of surgery in 43 patients who had given informed consent. Preoperative values were measured in 36 patients to establish the normal range. Fourteen patients underwent 'minor' surgery and 29 'major' surgery necessitating elective or emergency laparotomy. The severity of 'major' surgery ranged from cholecystectomy to pancreaticoduodenectomy. In all cases general anaesthesia was used.

In 13 patients with elevated SFP, reproducibility was evaluated by repeating the test at the same time. To confirm that aggregates were forming *in vivo*, individual tests were duplicated, in 6 patients on each occasion, in the following ways: (*a*) at 30 and 45 s after venepuncture; (*b*) in blood sampled into two syringes, one primed with EDTA and one without; and (*c*) via collection of simultaneous samples from basilic and femoral veins.

Clinical study

Twenty patients about to undergo elective 'major' surgery gave written informed consent and formed the basis of the study.

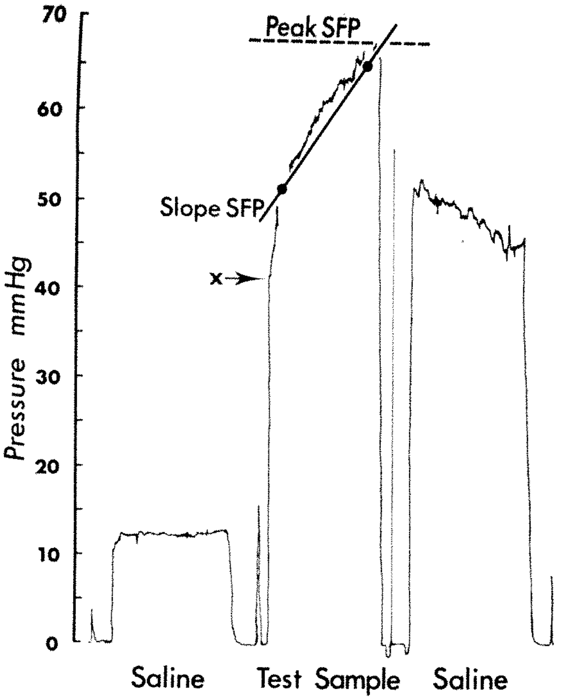

Fig. 1. The screen filtration pressure (SFP) waves produced by a sample of femoral vein blood, demonstrating peak SFP and the modified measurement of the SFP slope. Saline is passed before and after the test sample.

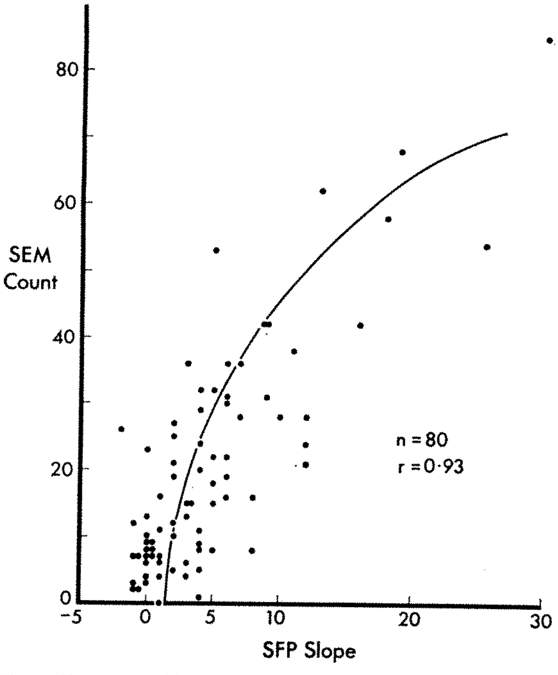

Fig. 2. The screen filtration pressure slope from 80 post-operative estimations correlates closely with the scanning electron microscopic count of the filter pores obscured by aggregates. The unit of SFP slope depends on recorder calibration; when multiplied by 0·214 it equals the pressure rise in mmHg/s.

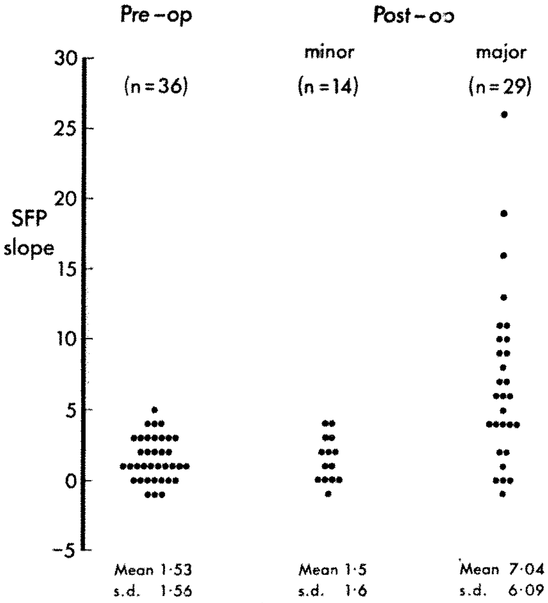

Fig. 3. Screen filtration pressure slopes in 43 patients before and within 30 min after surgery. The upper limit of normal is taken as 5 (*see* text). SFP slopes above this indicate the presence of intravascular platelet aggregates.

SFP was measured in femoral vein blood 30 min and 3 h post-operatively and, depending on the results, the patient was allocated to one of two groups—IPA-positive or IPA-negative.

Pulmonary function was evaluated preoperatively and post-operatively on days 1 and 7. Expired air was collected in a Douglas bag for a 5-min period. Arterial blood was taken simultaneously from the radial artery, through an indwelling parallel-sided 22-gauge Teflon cannula into a heparinized gas-tight syringe. Arterial $P\text{O}_2$, arterial $P\text{CO}_2$, expired $P\text{O}_2$ and expired $P\text{CO}_2$ were measured using gas electrodes. Alveolar $P\text{O}_2$ was calculated from the alveolar air equation of Filley et al. (1954) and physiological dead space from the Bohr equation (Bohr, 1891). All measurements were made in duplicate with the patient breathing room air. SFP estimations and pulmonary function measurements were performed by different investigators who compared results when the study was completed.

Detailed records were kept on other possible factors influencing pulmonary function, such as age, previous history of cardiopulmonary disease, smoking habits, medication, volume and nature of all intravenous infusions, together with serial changes in haemoglobin, white cell count and platelet count.

All operations were performed under general anaesthesia using intermittent positive pressure ventilation, nitrous oxide, oxygen and muscle relaxants being given with intravenous analgesia.

All statistical analyses were performed using the non-parametric Mann–Whitney U test.

Results

SFP evaluation

In 80 estimations, the correlation coefficient between peak SFP and the SEM count was 0·82. Although peak SFP is the parameter reported by previous investigators using this test, the slope of the SFP curve correlated more precisely, *r* equalling 0·93 in our patients (*Fig.* 2). This slope was measured from a point 2 s along the curve to a point 1 s prior to its termination, as interpretation of the initial point of this curve is subject to an unacceptable observer error (X in *Fig.* 1).

When the test was repeated at the same time in 13 postoperative patients, reproducibility was excellent ($r = 0{\cdot}95$). The SFP slope remained unaltered after a 15-s delay in performing the test (SFP at 30 s, mean 4·3, range 1–9; at 45 s, mean 4·6, range 0–8), and was not affected by the addition of EDTA to the syringe (SFP with EDTA, mean 5·7, range 0–12; without EDTA, mean 6·0, range 0–12). SFP was elevated only in femoral vein samples (mean 10·2) and not in samples taken simultaneously from the basilic vein (mean 1·4).

In 36 preoperative estimations and 14 following 'minor' surgery, the SFP slope remained below 5 in all but 1 (*Fig.* 3). However, in 29 patients following 'major' surgery, SFP elevation to greater than 5 was seen in 17. The mean SFP slope in this group was 7·1 ($\pm 6{\cdot}09$ s.d.), which is significantly higher than that after 'minor' surgery ($1{\cdot}5 \pm 1{\cdot}6$) or prior to operation ($1{\cdot}5 \pm 1{\cdot}56$, $P < 0{\cdot}001$). On this evidence intravascular platelet aggregates (IPA) were deemed to be present when SFP slopes were 5 or greater (mean preoperative $\text{SFP} + [2 \times \text{s.d.}] = 4{\cdot}7$).

Clinical study

Of the 20 patients in the clinical study, 10 proved to be IPA-negative (SFP slope <5) and 10 IPA-positive ($\text{SFP} > 5$). The mean sum of SFP at 30 min and 3 h was 2·4 (range −2 to 6) in the IPA-negative group, and 10·5 (range 6 to 24) in the IPA-positive patients. *Pulmonary function*: On the first postoperative day there was no difference between the two groups in any of the pulmonary function measurements (*Table I*). In the IPA-negative group mean preoperative arterial Po_2 (±s.e.mean) was 11·0 ($\pm 0{\cdot}55$) kPa and fell by 2·7 ($\pm 0{\cdot}48$) kPa on the first day after surgery. In the positive group this fall was 2·9 ($\pm 0{\cdot}36$) kPa. There was a wide scatter of change in physiological dead space (PDS) in the two groups, hence the mean rises of 4·1 ($\pm 19{\cdot}6$) ml in the IPA-negative group and 71·3 ($\pm 20{\cdot}1$) ml in the positive group were not significantly different. The rise in pulmonary arteriovenous shunt, denoted by the alveolar/arterial Po_2 gradient (A-ado$_2$), was marginally greater in patients with IPA ($2{\cdot}9 \pm 0{\cdot}66$ kPa) than in those without ($1{\cdot}9 \pm 0{\cdot}47$ kPa). This difference, however, was not significant.

One week after surgery the mean arterial Po_2 in the IPA-positive group was still 1·8 ($\pm 0{\cdot}38$) kPa below the preoperative value, whereas the mean arterial Po_2 in the IPA-negative group had recovered to only 0·6 kPa below its preoperative value. The difference between the two groups was statistically significant ($P < 0{\cdot}05$). The fall in arterial Po_2 in the IPA-positive group was due to an increase in pulmonary shunt, demonstrated by a rise in the alveolar/arterial oxygen gradient. The A-ado$_2$ rose from 3·8 ($\pm 0{\cdot}43$) kPa preoperatively to 6·1 ($\pm 0{\cdot}56$) kPa 1 week after surgery, a rise of 2·3 ($\pm 0{\cdot}43$) kPa or 61 per cent of the preoperative value. In the IPA-negative group the preoperative A-ado$_2$ of 4·3 ($\pm 0{\cdot}54$) kPa rose by only 0·4 ($\pm 0{\cdot}54$) kPa 1 week after surgery. This difference between the two groups was highly significant ($P < 0{\cdot}01$). The change in arterial Po_2 was not due to an alteration in the physiological dead space, which remained virtually unchanged in the two groups.

PDS, Physiological dead space.

Table II: INCIDENCE OF OTHER FACTORS WHICH INFLUENCE PULMONARY FUNCTION COMPARED IN IPA+ve AND IPA−ve GROUPS

	IPA−ve	*P*	IPA+ve
Age >60 (mean age)	6 (56·1)	n.s.	5 (61·3)
Previous history of cardiopulmonary disease	3	n.s.	2
Cigarette smokers	5	n.s.	7
Received blood transfusion (mean volume l)	3 (1·6)	n.s.	6 (3·1)
Mean fall in Hb day 1(g/dl)	1·6	n.s.	1·6
Mean fall in platelet count day 1 (10^9/l)	21·4	$P<0{\cdot}02$	81·7

Scanning electron microscopy of the screen filters from the IPA-positive group demonstrated multiple adherent aggregates up to 300 μm in diameter (*Fig.* 4). The major bulk of these aggregates consisted of platelets that on high power microscopy can be seen to have undergone marked morphological change (*Fig.* 5). In the IPA-negative group the filter surfaces were either clear or demonstrated small individual aggregates (*Fig.* 6).

There was no significant difference between the two groups with respect to age, medication, smoking habits or pre-existing cardiopulmonary disease (*Table II*). Six of the IPA-positive group received blood transfusion as did 3 of the negative group. The postoperative fall in Pao_2 and rise in A-ado_2 in the 9 patients who were transfused was marginally greater than in the 11 patients who received no blood transfusion, but these changes did not achieve statistical significance. The mean platelet count, however, in the positive group fell by 81·7 × 10^9/l 1 day after surgery. This fall is significantly greater than the fall of 21·4 × 10^9/l observed in IPA-negative patients ($P<0{\cdot}025$). Mean platelet levels returned to preoperative values over the following week.

Discussion

Intravascular microaggregates have not previously been demonstrated, or implicated, in the aetiology of postoperative hypoxaemia. Their detection in patients undergoing elective procedures such as ulcer surgery and colon resection had not been anticipated, especially as there was little previous evidence, even in severe shock, that they ever formed in substantial numbers. It was possible to examine the occurrence of the aggregates and their effect on pulmonary function once the SFP methodology had been modified and shown, on clinical application, to be reproducible.

Previous application of the Swank technique to evaluate patients gave disappointing results, possibly as these studies were performed in the laboratory on anticoagulated blood. Heparin, for example, is known to stimulate platelet aggregation, whereas the disaggregation stimulated by EDTA has been used as a measure of *in vivo* microaggregates (Wu and Hoak, 1974; Zucker, 1974). In this study, the apparatus was constructed on a standard ward dressing trolley and estimations were performed at the bedside. Thus, immediate and easily interpreted results are readily available in any clinical situation. The SFP curve has usually been evaluated using peak SFP (Swank et al., 1964; Dhall et al., 1969; McNamara et al., 1970), which, although accurate *in vitro*, would be influenced by the changes in blood viscosity and red cell deformability that may follow surgery. In this study the objective was to measure only the aggregates in blood, and the slope of the test curve correlated most accurately with their detection by SEM.

The technique was carefully standardized to eliminate variables due to sampling procedures. In our opinion the following four observations confirmed that the aggregates measured arose within the venous system: (*a*) the fall in platelet count over the 24-h operative period was greater in patients who had an elevated SFP; (*b*) priming of the syringe with EDTA prior to venepuncture did not alter the value of the SFP slope; (*c*) the SFP was no greater at 45 s than it had been at 30 s after venepuncture; (*d*) SFP levels may be normal in the arm, when simultaneously elevated in the femoral vein blood. This latter finding also suggests that aggregates may only form in regions of the venous system where, as a result of vasoconstriction, stasis accompanied by poor tissue perfusion commonly occurs. The failure to detect these aggregates in arm veins must also indicate that they are removed effectively by one circulation through pulmonary and peripheral tissue. For this reason, elevation of SFP in femoral blood in our patients could not result from the infusion of stored blood, which in every case was given via the arm veins.

Painful wounds and respiratory depression by drugs are important causes of sputum retention, segmented atelectasis and decreased lung volume; all these mechanisms are therefore important in the aetiology of low arterial oxygen tensions on the first day following surgery. The causes of persistent hypoxaemia, however, are less well documented. Although microaggregates have not previously been implicated in this condition, they have been found in the lungs and tissue of patients who have died after massive injury (Blaisdell et al., 1970). It was postulated that aggregates arose by a process of intravascular aggregation as a result of tissue trauma, hypoperfusion and ischaemia with subsequent release of vasoactive substances and lysosomal proteases. We formed the impression in our study that microaggregate levels were elevated in those patients in whom peripheral vasoconstriction had produced clinically obvious hypoperfusion of the feet with cold ischaemic toes. Hence we suspect that the metabolic products of tissue ischaemia, possibly combined with venous stasis, may have triggered platelet aggregation.

Transfusion of stored blood is known to affect pulmonary function adversely but this relationship failed to reach statistical significance in the patients we studied. The relationship between intravascular aggregation and pulmonary arteriovenous shunting seen in our patients may conceivably be coincidental. However, Dedichen and Kordt (1974) showed that the venous return from the legs usually exceeds 30 l/h during general anaesthesia, suggesting that the volume of aggregates from this source could be expected to have a greater effect on the pulmonary circulation than transfused bank blood. Normally aggregates are filtered out by the reticuloendothelial system in the lung, but if reticuloendothelial activity were deficient or overwhelmed by massive microembolization, this could lead to that condition known, in appropriate circumstances, as 'shock lung' (Pardy and Dudley, 1977). Our results suggest that this process, in a less severe form, occurs in many surgical patients. It seems possible, therefore, that persistent postoperative hypoxaemia may represent one aspect of a pathological spectrum which in its most severe form presents as the adult respiratory distress syndrome.

Our results indicate that screen filtration pressure is a reproducible measure of intravascular microaggregates which may be used immediately after surgery to predict pulmonary function 1 week later. These findings give tangible support to the hypothesis that intravascular aggregation leads to pulmonary microembolization. The method described may be used to evaluate scientifically the importance of intravascular aggregation and establish therapeutic regimens which, by preventing aggregate formation, may conceivably reduce postoperative hypoxaemia.

SUMMARY

Enterokinase is an enzyme produced by the mucosa of the small intestine. Its sole function is to activate trypsinogen to trypsin. In animals and man the duodenum and proximal jejunum have high levels of activity whereas the remaining small bowel has minimal levels.

A reproducible assay was developed for measuring mucosal enterokinase activity applicable to operative and endoscopic biopsies. Anaesthetic and operative techniques were developed for small intestinal resections in guinea-pigs to ensure their long term survival.

Transposition of high-enterokinase-secreting segments of guinea-pig small intestine to low-enterokinase regions and vice versa showed no alteration of enterokinase activity in the transposed segments. Similarly, resection of the enterokinase region in five proximal pancreaticoduodenectomy operations in man revealed no induction of enterokinase in the remaining jejunum at endoscopy 6 months later.

Isolation of high-enterokinase-secreting segments of small bowel from their luminal continuity by fashioning of Thiry–Vella fistulas led to a decay of enterokinase activity to minimal levels within 12–16 h. Perfusion of these fistulas with trypsin and sodium, or chymotrypsin and sodium, prevented this decay. If the enterokinase was allowed to decay over 24 h its activity could be restored to 80 per cent of its normal level by perfusion for 24 h with trypsin and sodium.

Trypsin and sodium act in combination on an enterocyte membrane receptor to stimulate enterokinase synthesis.

HEIDENHEIN showed in 1875 that freshly secreted pancreatic juice contains no active proteases. In 1900, Schepowalnikov, working in Pavlov's laboratory, discovered that pancreatic juice is activated by a duodenal factor which he named enterokinase. In 1939 Kunitz demonstrated that enterokinase is an enzyme which catalyses non-active trypsinogen to its active form—trypsin—by a first order reaction. A cascade reaction then occurs, as trypsin activates all the other proteolytic zymogens and prophospholipase in pancreatic juice. Without enterokinase therefore, the zymogens remain inactivated, digestion fails and protein starvation results (Hadorn et al., 1969).

Yamashina (1956) showed that enterokinase is a large glycoprotein (mol. wt $\simeq$ 200 000 : 30 per cent sugar) and that the activation of bovine trypsinogen was by hydrolysis of the peptide bond between lysine-6 and isoleucine-7, releasing active trypsin and its activation peptide Val-(Asp)$_4$-Lys.

Immunofluorescent studies using antiserum to pure human enterokinase have demonstrated its presence in man on the brush-border and glycocalyx of the enterocytes of the duodenum and proximal 10–20 cm of the jejunum (Hermon-Taylor et al., 1977).

This present study is designed to answer two questions. If the duodenum and proximal jejunum are removed, will enterokinase induction occur in the more distal small intestine and what factors control the mucosal synthesis of the enzyme?

Materials and methods

Mucosal enzyme assays

Enterokinase and aminopeptidase were assayed in 2–6-mg samples of fresh mucosa. After biopsy, the mucosal sample was washed in normal saline, gently blotted and weighed. For enterokinase it was immediately placed in 0·2 ml 70 mM Na succinate buffer, pH 5·6, containing 6·8 mM glycodeoxycholate (GDOC). Then 0·25 ml of a trypsinogen solution (1 mg/ml in 1 mM HCl with 2·2 mM CaCl$_2$) were added and the sample incubated for 30 min at 30 °C. The reaction was stopped by the addition of one drop of 2 M HCl. Of the supernatant, 0·2 ml were assayed for trypsin using N-α-benzoyl-L-arginine ethyl-ester (BAEE) (Baratti et al., 1973). Specific enterokinase activity was expressed as pmol trypsin min^{-1} mg^{-1}.

For aminopeptidase the fresh weighed biopsy was placed directly in 1 ml 50 mM Na phosphate buffer, pH 7·2, to which 0·1 ml of 16·6 mM leucine-p-nitroanilide (LPNA) was added. Incubation was for 15 min at 30 °C when the reaction was stopped with one drop 2 M HCl and the supernatant read spectrophotometrically at Δ_{405}. Specific aminopeptidase activity was expressed as pmol nitroanilide min^{-1} mg^{-1}.

Operative survival of guinea-pigs

Preliminary studies carried out with small intestinal biopsies from rats, rabbits, guinea-pigs, dogs and cats showed that the small intestinal enterokinase profile of guinea-pigs bore the closest resemblance to man. Unlike the rat it is difficult to carry out small intestinal resection and anastomosis in guinea-pigs and ensure long term survival. The following operative and anaesthetic details were found to be essential: SPF guinea-pigs must be used; 100 μg atropine 1 h before operation and repeated tracheal suction throughout; induction and maintenance of anaesthesia with 2 per cent methoxyflurane (3 l/min O$_2$+N$_2$O); monitoring and maintenance of body temperature at 38·5–40 °C during operation and afterwards until fully mobile; N saline 5 ml kg^{-1} h^{-1} s.c. Unlike in the rat, guinea-pig small intestine is fragile and anastomoses had to be performed using interrupted 6/0 chromic catgut sutures 1 mm apart everting the mucosa.

Studies using guinea-pigs

In 3 guinea-pigs the enterokinase and aminopeptidase profiles in the small intestine were established by multiple biopsies. In each of 6 guinea-pigs a 5-cm length of low-enterokinase-containing distal small intestine was transposed on its intact mesentery to the proximal high-enterokinase-secreting region. Enzyme levels were established in short segments from both ends of the transposed segment at the donor site and at the site of insertion. The animals were allowed to recover and were sacrificed at 3 months. A 5-cm segment of high-enterokinase-secreting proximal intestine was transposed to a distal low region in an identical manner in a further 6 animals; in both groups small intestinal enzyme profiles were measured after 3 months.

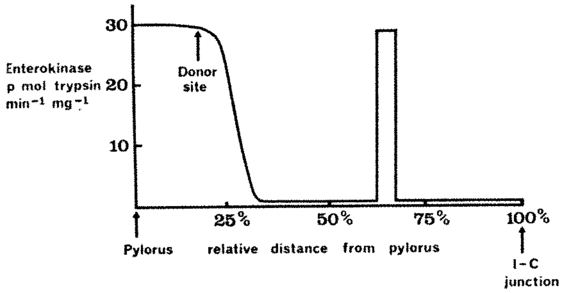

Fig. 2. Small intestinal enterokinase profile in the guinea-pig 3 months after transposition of a low-enterokinase-secreting segment of small intestine to a high-enterokinase region.

In a third group of 6 animals a 5-cm high-enterokinase-secreting segment was isolated from luminal continuity on its intact mesentery and brought to the anterior abdominal wall as a Thiry–Vella fistula. Enzyme levels were measured from both ends of the isolated segment at operation and after sacrifice 3 months later. In a further group of short term studies mucosal enterokinase and aminopeptidase levels were measured in Thiry–Vella loops of high-enterokinase segments at increasing intervals following isolation. Finally 24-h luminal perfusion of the isolated loops was carried out *in vivo* in a series of animals to identify factors which might affect mucosal enterokinase activity.

Clinical studies

Mucosal enterokinase and aminopeptidase levels were determined in the duodenum, and in the jejunum just beyond the site of division, in 5 patients during proximal pancreaticoduodenectomy for periampullary tumours. Enzyme levels in the afferent loops were also determined in these patients and in endoscopic biopsies 6 months later.

Results

The profile of mucosal enterokinase activity throughout the small intestine in 3 guinea-pigs is shown in *Fig.* 1. The length of the high-enterokinase-secreting segment was sharply localized to the proximal 20 cm distal to the pylorus; the mean maximal enterokinase activity in this segment was 27·5 ± 1·4 (s.d.). Enterokinase activity was always detected in the mucosa of the distal intestine but in the range 0·1–1·6 pmol trypsin min^{-1} mg^{-1} (pmT). In the same 3 animals aminopeptidase activity was evenly distributed throughout the small intestine; the range in each animal respectively being 0·87–1·37, 0·41–0·83 and 0·43–1·10 pmol nitroanilide min^{-1} mg^{-1} (pmN).

level in the segments before transposition was 0·58 ± 0·11 (s.d.) pmN and 0·48 ± 0·18 (s.d.) pmN 3 months later. The difference was not significant (*Fig.* 2).

The enterokinase levels in the distally transposed segments of proximal intestine in each of the 6 healthy animals at, and 3 months after, operation were 22·6 : 21·3, 31·0 : 30·0, 14·7 : 12·5, 22·6 : 19·7, 11·7 : 7·0 and 13·1 : 10·2 pmT respectively. The mean aminopeptidase level in the segments before transposition was 0·70 ± 0·19 (s.d.) pmN and 0·57 ± 0·17 (s.d.) pmN 3 months later. The difference was not significant (*Fig.* 3).

The enterokinase levels in the proximal small intestinal segments in each of the 6 healthy animals at, and 3 months after, isolation from luminal continuity were 12·1 : 1·0, 23·9 : 0·8, 18·8 : 1·1, 15·8 : 1·0, 19·7 : 1·3, 23·8 : 0·9 pmT. The mean aminopeptidase level in the segments before isolation was 0·63 ± 0·32 (s.d.) pmN and 3 months later 0·45 ± 0·14 (s.d.) pmN; the difference was not significant.

The time course of the decay of enterokinase activity in proximal small intestinal loops in 21 guinea-pigs at increasing intervals of time after isolation is shown in *Fig.* 4. Enterokinase activity fell to basal levels (0·4–2·2 pmT) by 16 h; aminopeptidase levels remained within the normal range. *Table I* shows that the decay in enterokinase activity was delayed by 24-h luminal perfusion *in vivo* of the isolated loops with solutions containing sodium ion, trypsin and chymotrypsin (Ca^{2+} was itself without effect but was included to prevent trypsin degradation). Perfusion with trypsin (1 mg/ml) and sodium (154 mM) in combination maintained enterokinase activity within its normal range. *Fig.* 5 shows that mucosal enterokinase activity in the isolated loops could be restored, after fall to basal levels, by 24-h luminal perfusion with a combination of trypsin and sodium, but not if the trypsin, although intact, was inactivated by TLCK* and not by trypsin or sodium alone. Chymotrypsin and sodium had an intermediate action on the restoration of enterokinase activity but papain and sodium was without effect.

Table II shows the enterokinase and aminopeptidase levels in three mucosal biopsies from the duodenum and divided jejunum at the time of proximal pancreaticoduodenectomy for periampullary tumour in 5 patients, and at endoscopic follow-up 6 months later. There was no increase in mucosal enterokinase activity in the remaining proximal jejunum.

Discussion

Assays similar to the ones described for the quantification of mucosal enterokinase have been used by other workers for the measurement of brush-border enzymes (Nordstrom and Dahlquist, 1971; Hadorn et al., 1974). The assay conditions described in the present study measured total available enterokinase since the majority of the enterokinase activity was present in the supernatant after incubation and transfer of the same mucosal sample to a second incubate showed minimal enterokinase activity. Furthermore, it has been pointed out by Scott et al. (1977) that the specific activities of other mucosal enzymes are best expressed per wet weight of fresh mucosa. The estimation of enterokinase in mucosal samples snap-frozen in liquid nitrogen and stored at −70 °C was inconsistent and all assays were carried out on fresh mucosa.

In the formation of Thiry–Vella fistulas Fabri et al. (1977) reported the survival of 4 out of 7 guinea-pigs. The difficulty of ensuring long term survival in guinea-pigs after intestinal resection is reflected in the paucity of reports on this subject in the literature. The initial mortality in intestinal resections which preceded the definitive ones in the present study was nearly 100 per cent; practice and the meticulous application of the perioperative and anaesthetic factors described, however, converted this to consistent near-total survival.

* Tosyl-Lysyl-Chloromethyl ketone (Sigma Chemical Co.).

The results in guinea-pigs are in close agreement with the clinical findings and show that enterokinase induction does not occur in the more distal small intestine when transposed to the environment of a high-enterokinase-secreting region. Maximum enterokinase secretion is maintained in the proximal intestinal segments in luminal continuity with the distal small intestine. Since one-day old guinea-pigs have an adult-type enterokinase profile, these findings suggest that a maximum permissible level of enterokinase synthesis at any site in intact small intestine is established in intrauterine life.

The maintenance of aminopeptidase levels in the normal range in isolated proximal small intestinal loops suggests that the rapid decline of enterokinase activity under these circumstances is not an artefact of surgical transposition. The enterokinase decay time of 12–16 h is in agreement with the reported rate of protein macromolecular turnover in intestinal mucosa (Alpers, 1977). The results of the perfusion studies suggest that maximal enterokinase synthesis by the mucosa is dependent upon a continued cooperative interaction of luminal trypsin and sodium ion. Further experiments are being designed to elucidate the molecular events responsible for this signalling mechanism. Whatever their complexities, it is clear that if the high-enterokinase-secreting segment of small intestine is removed, enterokinase will not grow back.

Plasma exchange and Raynaud's phenomenon—its assessment by Doppler ultrasound velocimetry

M. J. G. O'REILLY, A. J. DODDS, V. C. ROBERTS AND L. T. COTTON*

SUMMARY

In a group of 47 patients with Raynaud's phenomenon, Doppler ultrasound velocimetry was used to establish the severity of the disease by detecting the patency of the digital arteries. In conjunction with small digital occlusion cuffs, digital artery systolic pressure was measured on either side of the finger. A significant variation in systolic pressure was detected in each finger, and on each side of individual fingers. A more sensitive index of the severity of the disease was noted when the digital systolic pressure was compared to the brachial systolic pressure.

Plasma exchange, a potent method of lowering whole blood viscosity and plasma fibrinogen, was used to treat 18 of these patients. There was a significant improvement in digital vessel patency at both 21 °C and 13 °C after plasma exchange. Both the digital artery systolic pressure and the pressure index improved significantly after treatment.

As a result of the frequently reported incidence of raised blood viscosity (Pringle et al., 1965) and elevated fibrinogen levels (Jarrett et al., 1978) in patients with severe Raynaud's phenomenon, a rational method of treatment of these patients was considered to be plasma exchange which is known to reduce acutely blood viscosity and plasma fibrinogen (Pinching, 1978). Following the report of a pilot study (Talpos et al., 1978), a controlled trial was established to study the results of treatment in a group of patients with severe Raynaud's phenomenon.

Although plethysmography (Coffman and Cohen, 1971), arteriography (Downs et al., 1975) and isotope angiology (Hurlow and Strachan, 1978) have been reported as suitable methods of investigating the symptoms of patients with severe Raynaud's phenomenon, they may not accurately determine the degree of patency of the digital arteries. We determined to use Doppler ultrasound velocimetry following the report of Yao and his colleagues (1972) for, as Lewis (1929) had indicated: 'The signs and symptoms of Raynaud's phenomenon are a secondary manifestation of the abnormal sensitivity of the *digital arteries* to cold.' Doppler techniques are uniquely capable of detecting patency in individual vessels. In addition, with this technique, the patency of those digital vessels can be assessed under a variety of thermal stresses. Furthermore, the work of Nielsen and Lassen (1977), Lassen et al. (1977) and others has emphasized the importance, in these patients, of the intraluminal systolic pressure. This they measured plethysmographically. An alternative technique is to use the Doppler principle, with which the individual arteries can be directly insonated. The returning arterial flow, following release of a proximal occlusion cuff, can be immediately detected and the pressure at which this occurs (which is the digital artery systolic pressure) read from a mercury column.

Patients and methods

Forty-seven patients with severe Raynaud's phenomenon have been studied. Eight patients had severe digital ulcerations; 4 were known to have had digital ulcers which healed before treatment began. All patients were examined, lightly clothed, in a temperature-controlled laboratory at 20±1 °C.

After resting for 20–30 min, the fingers were insonated with a 10 MHz probe connected to an ultrasonic Doppler velocimeter. Insonation proceeded from proximal to distal phalange, on both the radial and ulnar sides of the finger. Each finger was considered as having available for insonation 6 digital artery segments, 3 radial, 3 ulnar. In both hands 56 digital artery segments were thus available for insonation. By counting the number of patent digital segments (i.e. those producing an audible Doppler shift on insonation), an estimate of the severity of the phenomenon in each patient could be obtained. This examination was then repeated after immersion of the hands for 1 min in water at 13 °C. Thus, following each of the temperature stresses, the number of patent digital arteries was obtained. This examination was repeated at 3-monthly intervals until a 9-month follow-up was reached.

Digital artery systolic pressure was also measured after each of the thermal stresses. A fine plastic (3-cm wide) cuff was placed around the proximal phalange. The digital artery on the radial side of the finger was insonated and the cuff inflated to suprasystolic levels. On cuff deflation, the returning arterial flow produced an audible Doppler shift readily detected by the probe. This procedure was repeated on the ulnar side of the finger and then for each of the fingers. This technique was also used to measure digital systolic pressure after each thermal stress. By comparing the digital systolic pressure to the brachial pressure (measured at the same time as the digital), a digital pressure index was obtained. A group of 10 normal control patients was examined in a similar manner on three occasions.

Eighteen patients were subjected to plasma exchange at weekly intervals for 4 to 5 weeks, 2·0–2·5 l of plasma being exchanged with equal amounts of purified protein fraction (PPF) and Haemaccel (Hoechst). Patients had blood removed before, after and mid-way between succeeding exchanges in order that blood viscosity, red cell deformability and plasma fibrinogen could be estimated.

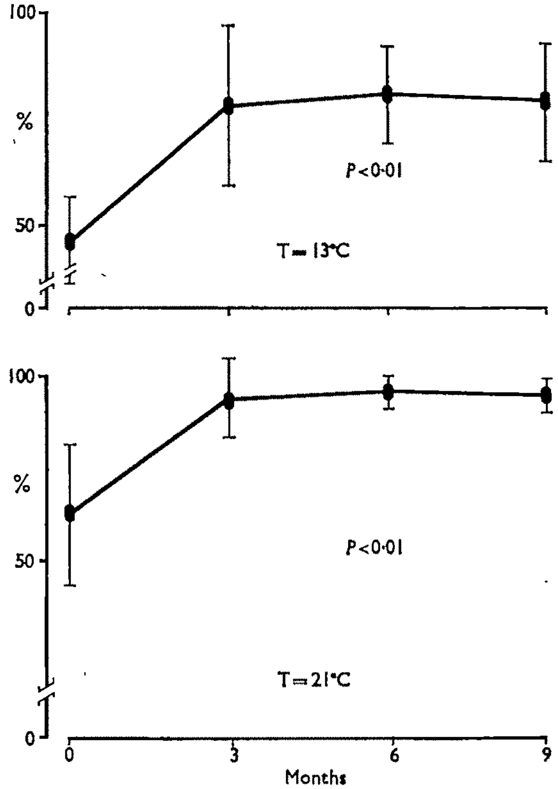

Fig. 1. Improvement in digital artery patency (per cent) after plasma exchange at 9-month review. Time 0 months indicates pre-treatment values.

Results

Using this technique of enumerating digital arteries we have found (*Fig.* 1) that the digital vessel patency (per cent) at 21 °C following plasma exchange improves from 63 per cent to 89 per cent at 9-month follow-up. Similarly, at 13 °C, the digital vessel patency improved from 46 per cent to 78 per cent. In both cases, this improvement was significant ($P<0{\cdot}01$ Student's t). In a group of 27 patients with Raynaud's phenomenon, the brachial systolic pressure was 131·0 ± 26·0 mmHg as compared to that in the control group of 115 ± 16·3 mmHg. These values were not significantly different. Before treatment, the digital pressure index at both 21 °C (*Fig.* 2) and at 13 °C (*Fig.* 3) was significantly lower than in the control group. Furthermore, it is noteworthy (*Fig.* 3) that at each temperature, the digital pressure index corresponding to both sides of the thumb was frequently less than in either the second, third or fourth fingers and similar to that of the fifth. The digital systolic pressure in all patients was less than in the control groups at 21 °C (*Fig.* 4) and the mean systolic pressure in the middle three fingers was always greater than in either the first or fifth fingers.

Following plasma exchange (*Fig.* 5), the thumb digital index measured at 21 °C was very similar to that found on the rest of the hand, although at 13 °C the variation noted before treatment still existed. However, there was no significant difference between the mean pressure indices of each of the second, third and fourth fingers at either 13 °C or 21 °C. All the pressure indices had improved after plasma exchange, although they were still less than in the control group.

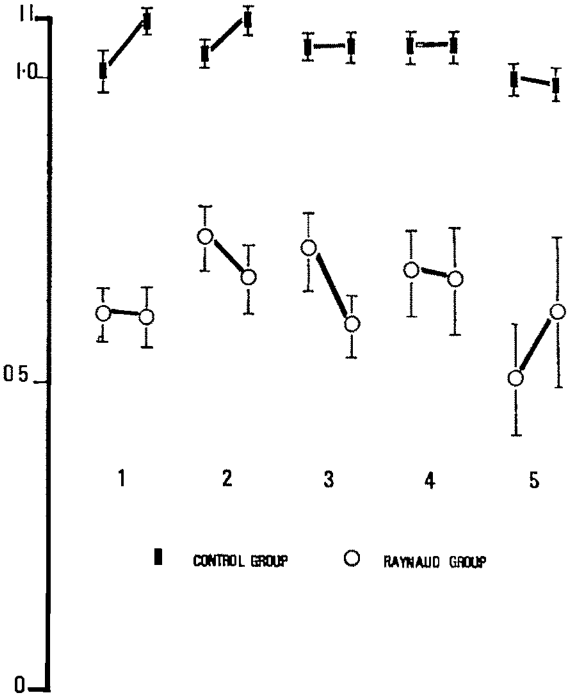

Fig. 2. Variation in digital pressure index at 21 °C in both the control group and the Raynaud group. The ulnar and radial indices of each finger are paired. Each finger is represented by a number. All ulnar values are on the left side of each pair.

At high shear rates ($91\ s^{-1}$) the viscosity levels measured in all 18 patients treated with plasma exchange did not significantly fall over the treatment period. However, both the whole blood viscosity when measured at low shear rate ($0{\cdot}77\ s^{-1}$) and the red cell deformability index (*Fig.* 6) did significantly improve when measured up to 90 days after plasma exchange ($P<0{\cdot}02$). In this group of patients plasma fibrinogen levels were less 90 days after plasma exchange than before, though not significantly so.

After plasma exchange the severe digital ulcers healed in all patients. Three, however, had no symptomatic improvement. Of the 10 patients who were purely symptomatic, 6 said they were better, 1 said she was worse, 2 showed an initial (3-month) improvement and then relapsed. One patient who had improved symptomatically 6 months after treatment felt at the last review (9 months) that his fingers had returned to their pre-treatment condition.

Conclusion

Doppler ultrasound velocimetry is a most useful method of measuring digital artery patency and thus can be considered a suitable means of correlating patients' symptoms with the distribution of patent arteries. Plethysmography can be used to measure either total hand (Peacock, 1960) or digital blood flow and to indicate intraluminal systolic pressure (Nielsen

and Lassen, 1977). However, Doppler ultrasound techniques are uniquely capable of measuring individual artery pressures rather than total digital pressure (Lassen et al., 1977). It correlates well with arteriographic and thermographic appearances of the digits and thus obviates the need for arteriograms in this relatively benign condition. Furthermore, it can be used quickly to assess digital artery systolic pressures and in our hands has produced values similar to those obtained by others (Nielsen and Lassen, 1977) using plethysmographic techniques.

It was of interest to note that the mean brachial systolic pressure was higher in these patients than in a control group of similar age and sex distribution. This may help confirm the impression that patients with Raynaud's phenomenon do have an increased generalized sympathetic tone (Coffman and Davies, 1975), although it is conceivable that the increased peripheral resistance, caused by the persistent vasospasm in the digital vessels was responsible for this mild hypertension. A vessel remains patent only when the intraluminal systolic pressure is greater than the tone exerted by the muscular walls of the vessel. In the presence of an elevated systemic systolic pressure, only by comparing the digital systolic pressure with the brachial pressure will an accurate estimation of the severity of the disease be obtained as the signs and symptoms in this condition are related to the pressure differential along the arterial segment and not the absolute intraluminal pressure. Our measurements have indicated that the major component of this differential pressure arises in the digital arteries themselves.

Plasma exchange is believed effective in this phenomenon as it may diminish part of the vasospastic component of the phenomenon by removing it from the patient's plasma. We have not yet been able to identify such a component. However, the reports of Gelin (1957) and others have indicated that blood flow in the small vessels and the microcirculation depends mainly on the flow properties of the blood; that is, blood viscosity haematocrit and red cell deformability. It is clear from these data that plasma exchange exerts a profound and long lasting beneficial effect on both the whole blood viscosity and the red cell deformability.

Simple enucleation and radiotherapy in the treatment of the pleomorphic salivary adenoma of the parotid gland

P. R. ARMITSTEAD, F. G. SMIDDY AND H. G. FRANK*

SUMMARY

A series of 76 patients with a primary pleomorphic salivary adenoma treated by simple extracapsular enucleation and high energy radiation between 1963 and 1976 is presented. Analysis of the results has shown a very low incidence of complications with only minimal cosmetic deformity. Of the 76 patients, only 5 have been lost to follow-up, 3 patients have died of causes unrelated to the tumour and only 1 patient has developed a recurrence. Further local excision in this patient showed the histological appearances of adenocarcinoma.

THE pleomorphic salivary adenoma is the commonest tumour to occur in the parotid gland, comprising 70–80 per cent of most published series. Because of its slow growth, encapsulation and the rarity of metastases, the tumour is often classified as benign; however, as with many other kinds of neoplasia, 'innocent' and 'malignant' are only relative terms.

Certainly the older surgical methods of treatment, consisting of intracapsular and later extracapsular enucleation alone, resulted in unacceptably high rates of recurrence (McFarland, 1936; Smiddy, 1956). Therefore, wide resection of the tumour by the operation of superficial conservative parotidectomy was advocated (Patey and Thackray, 1958). There is no doubt that after such a procedure the recurrence rate is low, but due to the facial nerve's intimate association with the parotid gland, the identification and preservation of the nerve during the course of the operation is mandatory. The risk of temporary, if not permanent, facial nerve damage during this dissection is quite high (Patey and Moffat, 1961). In 1956, Smiddy observed that when enucleation was followed by interstitial irradiation, no recurrences occurred in the small group of patients so treated. With the development of more sophisticated methods of external irradiation increasing numbers of patients have been treated by simple extracapsular enucleation and irradiation in the Yorkshire region. These patients have recently been studied retrospectively.

Patients and methods

Seventy-six patients with a primary pleomorphic adenoma of the parotid gland have been studied. There were 47 females and 29 males, whose ages ranged at presentation from 12 to 83 years. The distribution of patients in each decade is shown in *Fig.* 1. All the 76 patients complained of a swelling in the region of the parotid gland. The majority did not report to their general practitioner immediately due to the absence of pain and slow growth of the tumour (*Table I*). Only 6 of the 76 patients claimed that a recent increase in size had precipitated presentation. No patient had any facial nerve paresis on presentation. The parotid tumours in this series were more or less evenly distributed between the right and left glands, and no cases of multiple pleomorphic adenoma were seen.

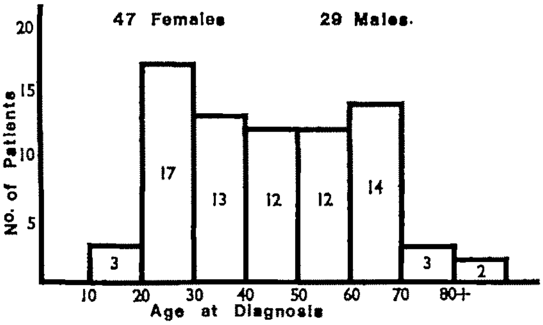

Fig. 1. Age distribution of 76 patients with primary pleomorphic parotid adenomas at time of presentation for treatment.

Table I: DURATION OF TUMOURS AT PRESENTATION

Duration	No. of patients	%
<1 mth	1	1·3
½–1 yr	17	24
1–5 yr	30	42
5–10 yr	19	27
10–20 yr	4	5·6

The majority of the tumours (45 per cent) were situated behind the angle of the jaw; however, others had produced diagnostic confusion by lying behind the ear, in the parotid tail, or high on the cheek. Most of the tumours arose in the superficial parotid tissue and only 2 were of the so-called dumb-bell type, extending through the narrow gap between the ascending ramus of the jaw and the styloid process and stylomandibular ligament to enter the parapharyngeal space. Ninety per cent of the parotid tumours were from 1 to 5 cm in diameter and only a minority were larger. Operative removal of the tumours was carried out through vertical incisions centred directly over the swelling followed by extracapsular enucleation or occasionally with an accompanying cuff of normal salivary tissue, particularly on the superficial surface. Occasionally it was necessary to display the facial nerve at its origin for tumours situated in its immediate vicinity. The wounds were closed in two layers over a soft drain and a firm dressing applied. It was apparent from the operative notes that rupture during dissection had occurred in some 16 of the 76 tumours.

All 76 patients received external irradiation when the skin wound had healed. This was given as supervoltage radiation in the form of cobalt-60 or Mev. linear accelerator radiation using two oblique beams which were modified by wedge filters thus optimizing the dose distribution to the parotid while decreasing the dose to the adjacent normal structures. A bolus was also strapped over the skin of the irradiated area so that the surgical skin incision received adequate irradiation. The patients received approximately 4800 rad, fractioned into fifteen treatments over a 3-week period.

Routine follow-up was carried out for the 5 years following the removal of the tumour. However, recently all 76 patients have been reviewed in the clinic or, if this was not possible, by means of a questionnaire to the patient or his or her general practitioner.

---

* Leeds General Infirmary, Great George Street, Leeds LS1 3EX.

Results

The parotid surgery was carried out by a variety of surgeons with varying degrees of surgical experience. There were some cases of facial nerve damage but in only 1 patient did this result in permanent disability. In a further 8 patients facial weakness, mainly involving the submandibular division of the facial nerve, was evident postoperatively, resolving spontaneously after a few months. Two patients developed salivary fistulas but these both closed following the radiotherapy. Frey's syndrome, with symptoms of gustatory sweating, was not found in any of the 76 patients. The only complications from the irradiation were some dryness of the mouth and desquamation into the external ear; however, appropriate dental prophylaxis was instigated before the radiotherapy.

The results of the recent follow-up of the 76 patients who had been treated by enucleation and postoperative radiotherapy are shown in *Fig.* 2. Only 5 patients could not be traced and their current status assessed. A further 3 patients have died, all from causes unrelated to their parotid tumours. To our knowledge only 1 patient has developed a recurrent tumour. This 68-year-old female developed a recurrence in the surgical scar 1 year after the initial treatment. This was excised locally but recurred twice more. On the third occasion histology showed adenocarcinoma and total parotidectomy was performed.

Discussion

Seventy-six patients with a primary pleomorphic adenoma of the parotid gland, treated by extracapsular enucleation of the tumour and postoperative radiotherapy between 1963 and 1976, are reported. The patients are comparable with other series (Wyatt et al., 1967; McEvedy and Ross, 1976; Woods et al., 1977) in that the age range was considerably greater than that found in malignant tumours of most other sites and that there was a female predominance. Late presentation for treatment was again a feature.

Enucleation alone results in a high recurrence rate (McFarland, 1936; Stea, 1975), probably due to the presence of residual peripheral nodules of the tumour (Patey and Thackray, 1958). Thus wide resection of this tumour was advised and this continues to be recommended as the treatment of choice (Maynard, 1978). Superficial conservative parotideciomy is, however, a difficult operation, and even when performed by an experienced surgeon, postoperative facial nerve damage is quite common (Patey and Moffat, 1961; Woods et al., 1977). Superficial parotidectomy is complicated by Frey's syndrome in 9–40 per cent of cases (Haws, 1975; Woods et al., 1977).

The recurrence rate following the removal of these tumours is, however, of paramount importance in determining the optimum initial treatment. Recurrences are usually multiple and can often undergo malignant transformation (Wyatt et al., 1967), as did one recurrent tumour in this series. The reported recurrence rates following superficial parotidectomy are low; Woods et al. (1977) reported 8 recurrences out of 360 operations. In our series of 76 patients treated by enucleation and radiotherapy only 1 tumour has recurred. Although long term follow-up in all the patients is not complete, most recurrent pleomorphic tumours occur early, many within 1 year, and nearly all within 5 years (Smiddy, 1956). Certainly the morbidity in this series is lower than would have been expected if superficial parotidectomy had been performed, particularly by general surgeons seeing only a small number of parotid tumours in a year. There have been several other recent reports of the treatment of parotid pleomorphic adenomas by enucleation and radiotherapy. McEvedy and Ross (1976) reported only 2 recurrences out of 73 tumours and Haws (1975) followed up 31 patients with only 1 recurrence. In both series the complications of the initial treatment were minimal and the cosmetic results excellent. It would therefore seem that when modern techniques of irradiation are combined with surgical enucleation the results are comparable with those of the more radical operations of conservative parotidectomy but without its inherent complications.

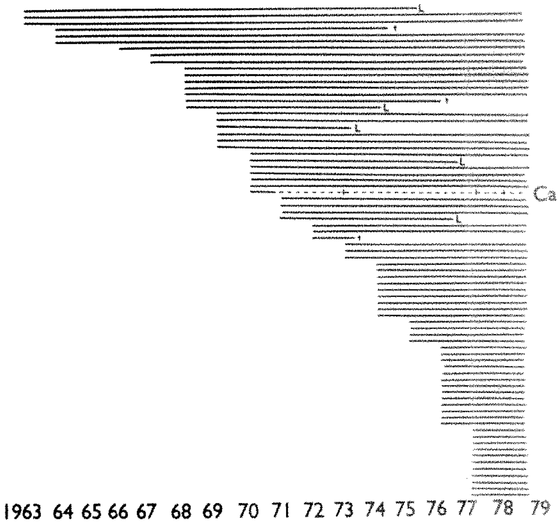

Fig. 2. Results of the follow-up of 76 patients with primary pleomorphic parotid adenomas. (†, Death; L, lost to follow-up.)

Segmental air plethysmography during arterial reconstruction

R. N. BAIRD, P. W. DAVIES AND D. R. BIRD*

SUMMARY

Sixty-one patients undergoing 83 lower limb reconstructions for chronic arterial ischaemia or aortic aneurysm from April 1977 to March 1979 were monitored intraoperatively using the pulse volume recorder (PVR), Doppler auscultation and palpation of pedal pulses. Nine technical defects (11 per cent) were recognized 5 min after declamping and corrected before the operative wound was closed. In 31 grafts to the popliteal artery median ankle PVR amplitude increased from 4·5 mm (95 per cent confidence limits, 2–6 mm) at the start of the operation to 18 mm (14–21 mm, $P<0{\cdot}0001$ *Wilcoxon). Four poor PVR wave forms were successfully improved by operative revision. Initial median calf PVR amplitude with isolated aortic or iliac artery occlusions in 30 limbs was 41 mm (29–56 mm), similar to that in 22 control limbs (38 mm, 28–53 mm), and did not alter following successful reconstruction. In this group there were 2 operative revisions and all grafts were patent postoperatively.*

*In successful proximal reconstructions of 22 severely ischaemic limbs with combined proximal and distal disease, median PVR amplitude fell from 10·5 mm (6·5–14 mm) to 8 mm (6·5–15 mm, not significant). There were 3 operative revisions and all grafts remained patent postoperatively. In this group with combined proximal and distal disease pulse wave transit time (*R *wave of ECG to peak calf PVR wave form) became shortened from 577 ms (542–633 ms) to 481 ms (467–495 ms,* $P<0{\cdot}05$*). Where operative correction was required, transit time on initial declamping became prolonged but fell to less than the pre-reconstruction transit time following successful revision. These results suggest that the information provided by intraoperative monitoring with the PVR will contribute towards a reduction in early graft occlusions and re-explorations in the postoperative period.*

THE pulse volume recorder (PVR)† is a new development in segmental plethysmography of the limbs in which a signal corresponding to the arterial pressure pulse is obtained non-invasively from an air-filled sphygmomanometer cuff (Raines et al., 1976; Baird and Davies, 1977). During the past year, preliminary reports have appeared describing the use of the PVR to monitor intraoperatively arterial grafting procedures (Bird et al., 1978; O'Donnell et al., 1978).

The pulse volume is monitored intraoperatively so that technical defects can be identified and corrected before the operative wound is closed. Failure to detect a substandard reconstruction at this time will result in early graft occlusion and expose the patient to the hazards of a re-exploration. Secondary operations have a high morbidity and mortality and the prognosis for graft patency is poor even with an early and apparently successful re-exploration (Craver et al., 1973).

Monitoring techniques were developed to combat early graft failures which, for femoropopliteal operations, range from 6 to 21 per cent (Renwick et al., 1968; Keitzer et al., 1972; Craver et al., 1973; Myhre, 1977). The results of proximal grafts to the iliac and femoral arteries are better, but in one series symptoms were not improved in 11 per cent, and some patients became substantially worse (Garrett et al., 1977). Following the introduction of routine intraoperative arteriography (Renwick et al., 1968; Taylor, 1978), electromagnetic flowmetering (Terry et al, 1972; Roberts and Cotton, 1977), use of a sterile Doppler ultrasound probe (Keitzer et al., 1972) and strain gauge plethysmography (Dickson et al., 1965), technical defects were detected in 15–34 per cent of arterial operations *at the time* so that corrections could be made before the reconstruction was completed (*Table I*). The results of reconstruction are related to the degree of preoperative ischaemia, but since the clinical indications for operations vary from one series to another, these results are not strictly comparable with one another. The proportion of limbs revascularized for rest pain or gangrene ranged from 18 per cent (Garrett et al., 1977) to 50 per cent (present series) and some authors (O'Donnell et al., 1978) excluded limbs in which Doppler pedal pulses were absent preoperatively.

Since our preliminary results with the PVR were encouraging, we embarked on a prospective trial of intraoperative monitoring, in which PVR amplitude and transit time were compared with Doppler transit time, the return of palpable or Doppler-audible foot pulses and the clinical outcome of operation.

Patients and methods

Of 147 patients who were monitored during arterial operations at Bristol Royal Infirmary in the 2-year period from April 1977 to March 1979, 61 (mean age 59 years) were studied who underwent reconstructions of 83 lower limbs for chronic ischaemia or aortic aneurysm (*Table II*). Operations for acute arterial ischaemia and reconstructions of the upper limb, carotid and renal arteries were excluded. Diabetes or abnormal glucose tolerance was noted in 9 per cent.

Lower limb ischaemia was evaluated clinically, by segmental limb PVR and Doppler systolic pressure measurements at the thigh, calf and ankle, and by arteriography. In all but 3 cases rest pain or gangrene was associated with an ankle pressure of less than 80 mmHg together with an ankle PVR amplitude of less than 10 mm (*Fig.* 1). More than three-quarters of proximal reconstructions in the presence of an occluded superficial femoral artery and of grafts to the popliteal artery were for ischaemic rest pain or gangrene. Proximal bypass of an isolated aortic or iliac artery occlusion was the most common operation for intermittent claudication (*Table III*).

Monitoring sphygmomanometer cuffs were applied to the calves for proximal grafts and to the ankles for grafts to the popliteal artery. The cuffs were applied firmly so that inflation with 75±10 ml of air resulted in a pressure in the cuff of 65 mmHg. A Perspex hood was placed over the feet to enable sequential Doppler auscultation and palpation of pedal pulses once sterile drapes had been applied. Recordings were made as follows: after establishment of stable anaesthesia; after mobilization of the arteries before clamping; 5 min after declamping; 30 min after declamping; 5 h later in the recovery room.

The output from the PVR was displayed on a strip chart recorder and, in addition, the wave forms were displayed for the surgeon on a storage oscilloscope. PVR, Doppler and ECG were recorded on FM cassette tape. PVR amplitude (mm) was measured from three consecutive wave forms, as was upstroke time (ms), defined as the time interval between the foot of the upstroke and the point of maximum deflection (Bird et al., 1978). Transit time was calculated from the R wave of the ECG to the peaks of the PVR and Doppler wave forms (Harper et al., 1974).

Since the distribution of data in most groups was heavily skewed all results are given as median values and 95 per cent confidence limits.

Statistical analyses were by the Wilcoxon matched pairs signed ranks test.

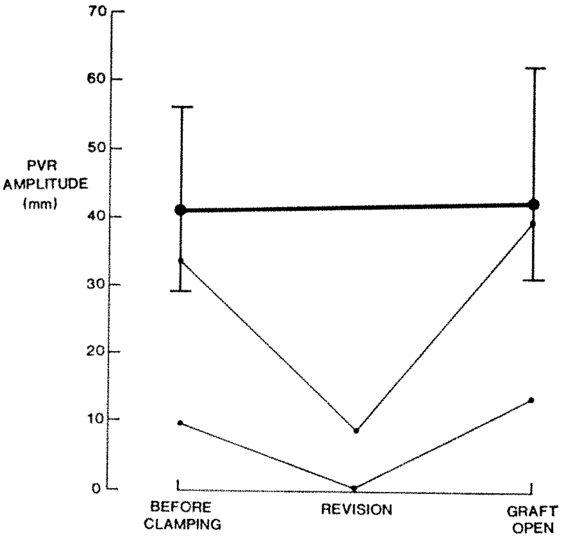

Fig. 4. PVR amplitudes in proximal reconstructions with a patent superficial femoral artery. Note the absence of resting ischaemia initially and the lack of change after declamping. In 2 cases a marked fall in amplitude occurred and operative revision was necessary.

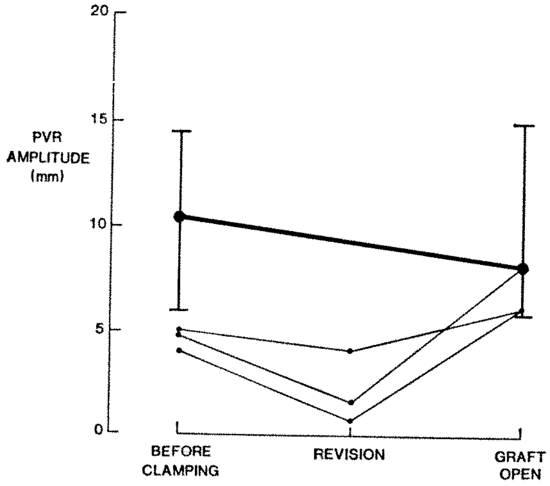

Fig. 5. PVR amplitudes in proximal reconstructions with an occluded superficial femoral artery. The initial amplitude is very low and does not increase immediately after successful reconstruction.

Results

Results were grouped as follows: grafts to the popliteal artery; proximal grafts for isolated aortic or iliac artery occlusions; and proximal grafts in the presence of an occluded superficial femoral artery. Control limbs were also studied.

Grafts to the popliteal artery (n = *31*)

Pulse volume recordings (*Fig.* 2): The initial median ankle PVR amplitude was low at 4·5 mm (2–6 mm), and in successful grafts there was a fourfold increase in PVR amplitude to 18 mm (14–21 mm, $P<0.0001$). A poor initial result shown by decreased PVR amplitude in 4 vein grafts was improved by insertion of a vein gusset at the proximal anastomosis (*Fig.* 3). One vein graft was attached to a previously inserted aortofemoral Dacron graft, and balloon catheter embolectomy was required to remove fragments of intima from the Dacron/vein anastomosis. All revised grafts subsequently remained patent.

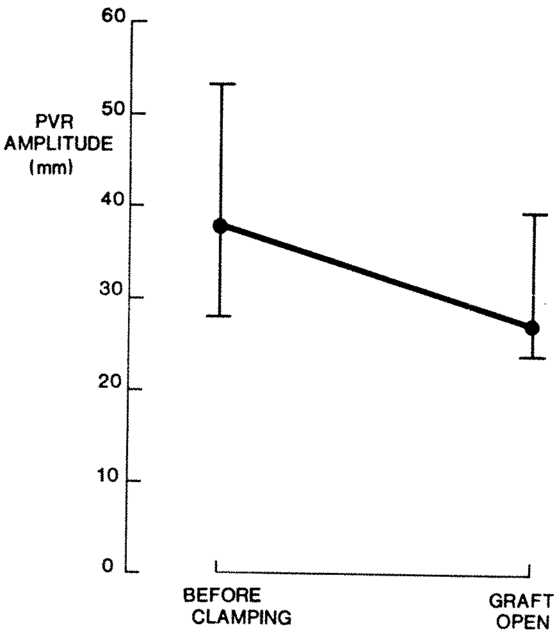

Fig. 6. Calf PVR amplitude changes in 22 control limbs. Recordings were made at the same stages as for the operated limbs. Note the fall in amplitude.

Pedal pulses: Preoperatively a Doppler pedal pulse was heard in all but one of the limbs but a pedal pulse was palpable in only one limb. At the end of operation Doppler pulses were invariably present but a palpable pulse was present in only one-quarter of the vein grafts studied.

Outcome: Two vein graft failures within the first 5 days were due to use of a vein of inadequate size (<4 mm diameter). Heparin (for DVT) induced anastomotic haemorrhage necessitating reoperation in 3 limbs, which in turn resulted in thrombosis of 2 vein grafts. Fourteen of 18 vein grafts (78 per cent) were patent at discharge from hospital.

Grafts to the iliac, common femoral and profunda arteries

Superficial femoral artery patent (n = *30*): The initial PVR amplitude was normal (41 mm, 29–56 mm) and following a successful reconstruction, a similar value (42 mm, 31–62 mm) was obtained (*Fig.* 4). Two operative revisions (balloon catheter embolectomy and graft extension from the iliac to the femoral artery) were required because the initial post-reconstruction wave form disappeared in one instance and was severely damped in the other, amplitude falling to only 24 per cent of the pre-reconstruction value (from 34 mm to 8 mm). All grafts remained patent postoperatively, with early return of pedal pulses.

Superficial femoral artery occluded (n = *22*): These limbs were severely ischaemic preoperatively with a

PULSE VOLUME RECORDER (PVR®)*

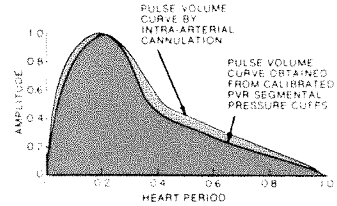
The NON-INVASIVE Clinical Vascular Laboratory

An Extensively Documented Clinical Procedure for the Quantitative Evaluation of Peripheral Vascular Disease:

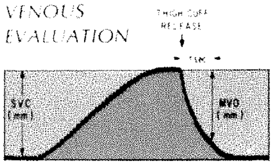
Arterial — Venous — Cerebral

Excellent Long-term Reproducibility and Calibrated Accuracy by Quantitative Segmental Cuff Technique

Ophthalmic artery pressure is read directly on the OPG Attachment of the PVR for the evaluation of collateral circulation to each eye, and its respective cerebral hemisphere.



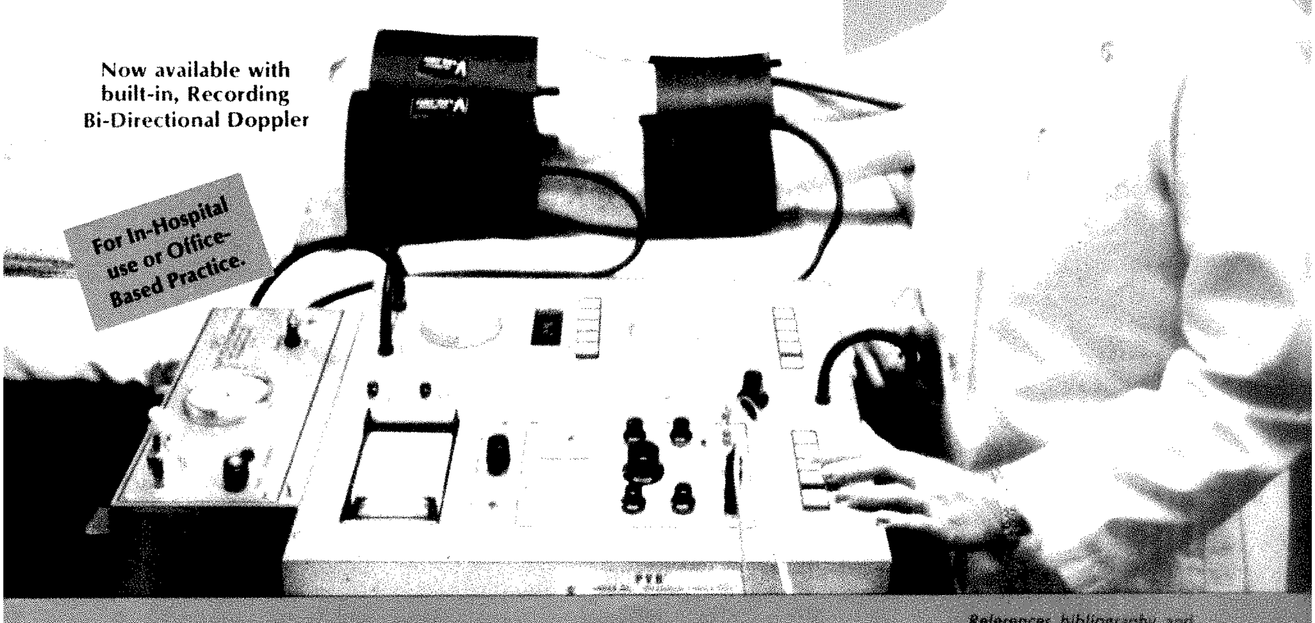
Comparison of pressure contours obtained with the PVR and direct cannulation of the common femoral artery.



A 15-point scale provides approximately 5% false (+) and 2% false (-).

Total Segmental Perfusion (primary vessel plus collaterals) is accurately documented at the thigh-calf-ankle-metatarsal level and digits. The built-in Doppler facilitates the measurement of pressures along the arterial tree.

The COMBINED information of segmental PVR recordings and systolic pressure gradient establishes a clinically accurate picture of functional perfusion.



Now available with built-in, Recording Bi-Directional Doppler

For In-Hospital use or Office-Based Practice.

*** As Developed by The Vascular Laboratory, Dept. of Surgery, Massachusetts General Hospital, Boston, Mass.**

Good reasons for choosing the Seward minor operating table

"It's got everything I need – full marks for design, versatility and safety."
"We looked for the best all-round value and this was definitely the one."
"I weigh 280 pounds or 127 kilos – it's strong enough for me."
"Excellent choice of accessories for general theatre use and our accident-emergency department."
"And there's an X-ray translucent top for me."

Hospitals in many parts of the world have chosen the Seward minor operating table. Because it has so many advantages — at a very competitive price . . .
Superb design quality — with stainless steel table-top and side rails.
Safety for the patient — instant tilt release into Trendelenberg and reverse Trendelenberg positions. Easily adjustable head and foot sections.
Accessories — wide range available from Seward.

Strong, handsomely styled, easy to keep clean. The ideal operating table for many surgical procedures, accident, casualty and outpatient departments. Send now for full details and a price list.

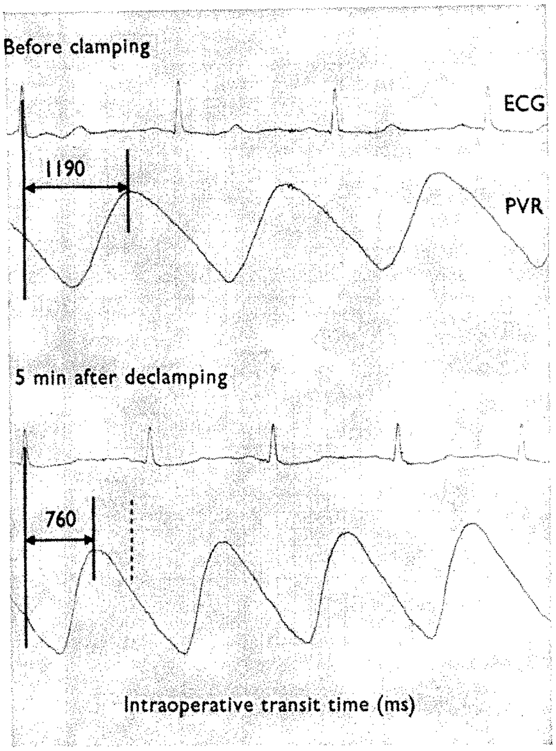

Fig. 7. Following successful proximal reconstruction of an occluded iliac artery, transit time from the R wave of the ECG to peak calf PVR wave form was reduced from 1190 ms to 760 ms. Note the absence of change in PVR amplitude.

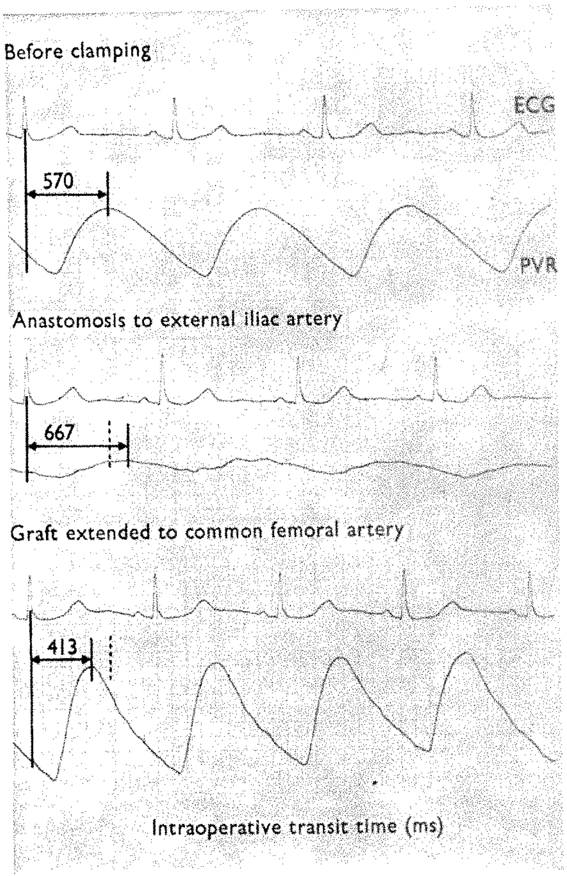

Fig. 8. A poor initial result (centre) after aorta-to-external-iliac reconstruction. Note that the transit time became reduced to less than the initial value after successful revision to the common femoral artery (bottom).

low initial calf PVR amplitude of 10·5 mm (6·5–14 mm) which was insignificantly altered to 8 mm (6·5–15 mm) after a successful reconstruction (*Fig.* 5).

In 3 cases deterioration in the initial post-reconstruction wave form prompted operative revision (balloon catheter embolectomy in 2, graft extended from iliac to femoral artery in 1). This deterioration was detected in 2 cases by an increase in transit time. No pedal pulses were palpable in any limb at any stage and ankle Doppler signals were absent in 23 per cent and indecipherable in a further 18 per cent. All grafts remained patent postoperatively.

Control limbs (n = *22*)
PVR wave form amplitude fell from 38 mm (28–53) to 27 mm (23–39 mm, $P<0{\cdot}02$) during the reconstruction (*Fig.* 6), but amplitude was restored to normal in the recovery room. The controls were contralateral limbs during femoropopliteal reconstructions and lower limbs during subclavian and axillary artery reconstructions.

Effect of arterial dissection: Mobilization of the arteries at the sites of proximal and distal anastomoses occasionally resulted in a reduction in PVR amplitude greater than that observed simultaneously in control contralateral limbs, although in all three groups of patients PVR amplitude before and after arterial dissection was not significantly different. The most marked changes were seen after aorto-iliac dissection in patients with rest pain or gangrene, and in 4 limbs in this group the PVR wave form was completely lost after dissection along with pedal Doppler signals. These changes were not associated with a reduction in the brachial systolic pressure.

Transit time: In limbs with combined proximal and distal occlusions, transit time was initially prolonged at 577 ms (542–633 ms) compared with limbs with patent distal systems at 455 ms (430–503 ms) or with Harper's age-matched control subjects (403 ms) (Harper et al., 1974).

In 23 proximal reconstructions where the distal arteries were patent, transit time fell to near normal values, and an illustrative example is given in *Fig.* 7. Ankle Doppler velocity/time wave forms were always present at the start of operation and Doppler transit time correlated well with PVR transit time ($r = 0{\cdot}96$).

Following successful proximal reconstruction in the presence of distal disease, transit time at 5 min after declamping was significantly shortened (481 ms, 467–495 ms, $P<0{\cdot}05$). In two instances where a revision was necessary, transit time was prolonged on initial declamping (from 570 to 667 ms and from 493 to 607 ms) and was only reduced to less than the pre-reconstruction value after operative corrections were made (*Fig.* 8). In this group calf PVR wave form was used to calculate the transit time because in only

4 of 7 limbs could a usable Doppler signal be detected at 5 min after declamping.

In separate studies of patients under general anaesthesia, the effects of alterations of heart rate and systemic blood pressure on transit time were measured. The heart rate was increased from 65 beats per minute to 110 beats per minute by administration of graded increments of atropine and isoprenaline. The transit time responded by becoming steadily shortened at the rate of 1·5 ms per unit increase in heart rate. Introduction of this correction factor did not affect the significance of the examples illustrated or the overall results. Transit time was not affected by fluctuations of brachial systolic pressure in the range of 85–135 mmHg.

Discussion

A prompt and substantial increase in PVR amplitude at 5 min after declamping a graft to the popliteal artery allowed the wound to be closed without delay and with confidence that a successful result had been obtained. The PVR signal was equally satisfactory for both femoropopliteal and iliopopliteal grafts. If, when the PVR was repeated at 30 min, there was confirmation of a good technical result, the probability of graft patency was high. Detection of palpable pulses in only 25 per cent of grafts suggests that pulse palpation at this vital stage is an unreliable method of assessment. Inspection of the feet was also found to be an insensitive method since more than half the patients with successful grafts did not lose the coldness and pallor of the ischaemic foot until in the recovery room or later.

Measuring lower leg perfusion immediately after a proximal reconstruction in the presence of an occluded outflow tract is perhaps the greatest test of a monitoring system; in this group of technically demanding reconstructions for severely ischaemic limbs the preliminary results of PVR transit time measurements are most encouraging. It should not be forgotten that a functionally inadequate graft in a heparinized patient may pulsate vigorously, only to thrombose a few hours later.

In this group PVR amplitude at 5 min is not a reliable indicator of an effective reconstruction, although graft revision was necessary if PVR amplitude upon declamping was less than 38 per cent of the initial value. These results confirm earlier reports (Raines et al., 1976; O'Donnell et al., 1978).

Although PVR amplitude may be unhelpful in this group, PVR upstroke time is significantly reduced in successful grafts and is reliably associated with postoperative patency (Bird et al., 1978). This increased wave form pulsatility is also manifest as a reduction in transit time, which has been measured in young and old normal subjects (Harper et al., 1974) and in the diagnosis of arterial occlusive disease (Craxford and Chamberlain, 1977) but not hitherto for intraoperative monitoring,

A useful feature of the PVR monitoring technique is its simplicity and ease of interpretation. Increased amplitude in grafts to the popliteal artery or shortened transit time in proximal grafts is associated with a successful clinical outcome. If the anticipated PVR improvement is not present at 5 min after declamping, effective remedial action can be taken without delay. The success of any operative revision can be readily confirmed. The recordings are stable and can be made by a nurse in the operating theatre or recovery room.

Our results suggest that the PVR is a significant advance in intraoperative monitoring and that the information it provides will contribute towards a reduction in graft occlusions and re-explorations in the early postoperative period.

Long term results of autogenous vein bypass grafts in femoropopliteal arterial occlusion

R. P. GRIMLEY, M. L. OBEID, F. ASHTON AND G. SLANEY*

SUMMARY

The results of 329 consecutive autogenous vein grafts carried out between January 1962 and June 1973 have been reviewed. The 5- and 10-year mortality rates were 14·6 per cent and 18·7 per cent respectively.

The corresponding patency rates were 70 per cent at 5 years and 34 per cent at 10 years, the lowest patency (27·8 per cent) occurring in below-knee anastomoses with grafts of 5 mm or less in diameter. As others have noted, the state of the popliteal–tibial run-off vessels had a considerable influence on long term patency rates. In severely ischaemic limbs, the limb salvage rate following this operation was 77 per cent.

An analysis of symptoms, associated disease and complications is presented and discussed.

No valid conclusions could be made regarding the effect of lumbar sympathectomy and postoperative anticoagulants on long term patency.

This review has confirmed the findings of earlier studies that a satisfactory 5-year patency rate and a gratifying limb salvage rate can be achieved with an extremely low operative mortality rate of 0·37 per cent. Despite the presence of widespread atherosclerotic arterial disease, the 5-year mortality rate is 14·6 per cent, indicating that an attempt at reconstructive surgery is usually well worth while.

THE 5-year results following femoropopliteal venous bypass grafts were reported from this unit in 1970 (Baddeley et al., 1970). Since results utilizing alternative graft prostheses are being reported we considered it worth while to review our own series in which some patients have now reached 12-year follow-up.

Patients and methods

From January 1962 to June 1973, 329 autogenous vein grafts were implanted in 272 patients, of whom 22 were women. Symptoms were bilateral in 138 patients, of whom 57 required bilateral surgery (18 per cent of the total number). Twenty-one patients were lost to follow-up; a further 26 patients had left the area but adequate data were obtained from their general practitioners.

The influence of age on graft failure is summarized in *Table I*. Most patients were aged 50–69 years and the largest number of graft failures—61·3 per cent—was observed in the 40–49 age group. The overall mean failure rate in the under-50 age group (47·5 per cent) was slightly higher than in the over-50 age group (40·6 per cent), but there are obvious differences in the number of operations performed.

Presenting symptoms were disabling intermittent claudication in 264 limbs, rest pain was present in 65 limbs and 21 limbs had trophic changes; both rest pain and trophic changes were present in 37 limbs. An analysis of type and duration of symptoms is presented in *Table II*. Four patients with superficial femoral artery trauma and 11 with distal limb aneurysms are also included.

In patients with signs of advanced ischaemia and intermittent claudication of more than 2 years' duration, the trophic changes were relatively recent events precipitating surgical referral. In 124 limbs symptoms had been present for 1 year or longer; the remaining 168 had shorter histories necessitating earlier operation because of advanced ischaemia.

Table I: AGE DISTRIBUTION

Age (yr)	No. of limbs	Eventual graft failure No.	Eventual graft failure %
Under 40	15	5	33·3
40–49	44	27	61·3
50–59	112	50	44·6
60–69	138	55	39·8
70–77	18	5	27·8
80–89	2	1	50·0

Table II: DURATION AND TYPE OF SYMPTOM

Type of symptom	Duration <6 mth	6–12 mth	1–2 yr	2–3 yr	>3 yr	Total
IC	27	42	39	16	20	141
RP	4	2	—	—	—	6
T	1	1	1	—	—	3
Other	7	1	—	1	1	10
T+other	1	—	1	—	—	2
IC+RP	18	18	18	2	9	65
IC+T	6	8	5	1	1	21
RP+T	3	2	—	1	1	7
IC+RP+T	12	12	5	4	4	37

IC, Intermittent claudication; RP, rest pain; T, trophic change (including 3 patients with frank gangrene); other symptoms relate to superficial femoral artery trauma and limb aneurysms.

Of the 141 claudicants, 121 had had symptoms for more than 6 months and 118 had a measured walking distance on a flat hospital corridor of 200 yards (185 m) or less. The majority of the patients were operated upon before routine Doppler assessment became available.

Arteriography, electrocardiography, biochemical and haematological profiles were performed routinely. Dyspepsia was investigated because of the potential problems associated with anticoagulation and to exclude malignancy.

At annual follow-up grafts were designated patent if the graft or pedal pulses were palpable; a few were investigated by further angiography because of subsequent symptoms in the contralateral limb or proximal aorto-iliac disease. In the majority of cases symptoms and signs of ischaemia were relieved. In 8 patients with a patent graft ischaemia progressed owing to progressive occlusive atherosclerotic disease in the run-off vessels.

Results

Of the 329 grafts, 134 occluded during a follow-up period of 6 months to 13 years, mean follow-up being 6·53 years.

Mortality

Of 272 patients, 60 (22 per cent) died from causes shown in *Table III*. Only 1 patient died postoperatively—an operative mortality of 0·37 per cent. The late mortality at 2 years, 5 years and 10 years was 5·1, 14·6 and 18·7 per cent respectively.

In the deceased patients 34 grafts were patent and 31 occluded, so that the percentage of grafts functioning at the time of death was 52.

Graft patency

The percentage patency was calculated from survivors alone. Thus 137 grafts were followed up for 5 years or more and of these 96 were patent—a 5-year patency of 70·08 per cent. In *Table IV* it can be seen that patency falls markedly from 69·51 per cent to 34·48 per cent after 7 years' follow-up.

Arteriograms were available for review in 297 of the patients with atherosclerosis. In 134 less than 15 cm of the femoropopliteal segment was occluded and in 163 cases more extensive occlusions were present, graft patency being 67·9 per cent and 63·8 per cent respectively. These similar patency rates indicate that the graft is an efficient bypass around the diseased segment. The alternative surgical technique, thromboendarterectomy, is inadequate in this respect, as we have already emphasized in our earlier reports (Baddeley et al., 1968).

Table III: CAUSES OF DEATH

Cause of death	No. patients	Total grafts	Occluded grafts	Patent grafts
Cerebrovascular accident	14	15	9	6

Patency related to popliteal–tibial run-off

In a previous report, run-off was graded as follows: 'excellent' with normal popliteal and tibial vessels; 'good' when minimal disease of the popliteal and tibial arteries was present; 'moderate' with 'scalloping' of the popliteal artery and occlusion of one of the three main calf arteries or narrowing of the others; 'poor' when two or all three calf arteries were occluded (Baddeley et al., 1970).

The patency rates, summarized in *Table V*, for good and moderate run-off were satisfactory, with 5-year patency rates of 75 per cent. Patency declined after this time, however, especially where run-off was only moderate, with a resultant 10-year patency rate of 10 per cent. Initial patency rates in the poor run-off group were comparable to the 5-year rates in the better groups, but 5 years postoperatively only 50 per cent of grafts remained patent and all of these had occluded by the eighth postoperative year. Of the 22 patients whose grafts occluded in this group only 9 required a major amputation.

Patency, site of distal anastomosis and graft diameter

The minimal diameter of 312 implanted grafts was noted at operation. The outcome of these grafts is summarized in *Table VI* with a mean follow-up of 6·53 years.

The diameter of the graft was greater than 5 mm in 271 cases, but it is evident that above-knee grafts are associated with higher patency regardless of diameter. Grafts inserted at the level of the knee joint have satisfactory patency values where the calibre is greater than 5 mm.

Very poor results were found in vein grafts of small calibre inserted below the knee joint. Since poor run-off could influence the poor results of below-knee grafts, run-off studies were correlated with the site of distal anastomosis (*Table VII*).

Patency rates with below-knee anastomoses are lower than with above-knee anastomoses whatever the degree of atherosclerosis in the run-off vessels. Our series firmly supports the view that below-knee grafts of small calibre inserted into limbs with poor run-off usually fail.

Table V: DURATION OF FOLLOW-UP AND GRAFT PATENCY IN PATIENTS WITH GOOD, MODERATE AND POOR POPLITEAL TIBIAL RUN-OFF

	Good			Moderate			Poor		
		Patency			Patency			Patency	
Duration	Grafts	No.	%	Grafts	No.	%	Grafts	No.	%

NB, Patency rate is calculated from survivors alone.

Limb salvage

Advanced ischaemia (pain, trophic changes, including ulceration or gangrene) indicating immediate amputation was present in 185 legs. The autogenous vein grafts remained patent in 101 of these and occluded in 84; of these, a major amputation was subsequently necessary in 42 cases. Thus, 143 limbs were salvaged (77·29 per cent). Terminal ischaemic changes, ulceration or gangrene were present in 69 limbs, in which 30 grafts remained patent and 35 out of 69 (50·73 per cent) limbs were salvaged. It was of interest that, as indicated in an earlier study, subsequent failure of a graft does not always necessitate amputation. Therefore, in spite of late graft failure, a functioning limb may remain, albeit with some degree of vascular insufficiency (Baddeley et al., 1970).

Complications of surgery

Reports in the literature are scarce, but our records revealed that potentially avoidable complications account for significant morbidity and should receive further attention. Graft patency was not affected by these complications.

Wound complications

Very few wounds discharged frank pus. The incidence of other complications was as follows: sepsis, sloughing, lymphorrhoea and delayed healing, 19·55 per cent (61 limbs); leg oedema, 17·67 per cent (54 limbs); saphenous neuralgia, 3·2 per cent (10 limbs); pulmonary embolism, 2·9 per cent (9 patients); DVT (confirmed), 0·64 per cent (2 limbs); postoperative bleeding, 0·64 per cent (2 limbs).

The site and size of the graft had no relation to the relevance of complications, but oedema was most common following anastomosis below the knee joint (23 out of 107 grafts).

Concomitant sympathectomy

In 68 limbs lumbar sympathectomy was performed at the same time as reconstructive surgery. Numbers are too small for useful comparison, however, but preliminary analysis indicates that patency was less influenced by sympathectomy than by the state of popliteal run-off, graft diameter and the level of the anastomosis.

Postoperative anticoagulant therapy

Phenindione or warfarin therapy was begun 48 h postoperatively and continued without interruption after 100 operations. Unfortunately, selection was uncontrolled, but marginal benefits were apparent where run-off was moderate and veins were less than 5 mm in diameter.

Associated disease

Of 213 cases operated on, diabetes was present in 14·5 per cent, ischaemic heart disease in 59·6 per cent, hypertension in 38·1 per cent and 8·1 per cent had sustained cerebrovascular accidents. As might be expected, the outlook is not quite as satisfactory when widespread disease is present, with an overall patency rate of approximately 50 per cent, as indicated in *Table VIII*. However, in view of the low operative mortality rate these associated conditions are certainly not contraindications to reconstructive surgery.

Table VI: PATENCY, SITE OF ANASTOMOSIS AND CALIBRE OF GRAFT

Anastomosis level	Diameter of graft (mm)	No. grafts	Occluded	Patency No.	%
Above-knee	<5	21	8	13	61·9
Above-knee	>5	170	64	106	62·36
At knee	<5	2	1	1	50.00
At knee	>5	12	4	8	66·6
Below-knee	<5	18	13	5	27·78
Below-knee	>5	89	42	47	52·81

Table VII: PATENCY RELATED TO RUN OFF STATUS AND LEVEL OF GRAFT INSERTION

Run-off	Anastomosis level	No. grafts	Occluded	Patency No.	%
Good	Above-knee	80	23	57	71·25
	Below-knee	35	19	16	45·71
Moderate	Above-knee	46	17	29	63 09
	Below-knee	27	14	13	48·14
Poor	Above-knee	22	11	11	50·00
	Below-knee	24	18	6	25 00

Table VIII: ASSOCIATED DISEASE AND GRAFT PATENCY

Disease	No. grafts	Occluded grafts	Patency No.	%
Cerebrovascular accident	17	8	9	52·94
Diabetes	31	15	16	51·61
ECG change	125	44	79	63 20
Hypertension (>95 mmHg systolic)	80	38	42	52 50
Other (mainly DU)*	46	25	21	45·64

Discussion

Our results reaffirm that the reversed saphenous vein graft currently remains the best reconstructive procedure for femoropopliteal occlusive disease. Our 5-year patency is higher than that in our earlier series (Baddeley et al., 1970) and that reported by De Weese and Robb (1977) but it remains lower than in some other series (Darling et al., 1967; Cutler et al., 1976). There is general agreement that run-off is most important and this series confirms this view. Cutler et al. (1976) found no significant difference between patency rates for grafts inserted for mild ischaemic symptoms or for advanced disease, the determining factor being vessel run-off.

Other graft materials are currently being evaluated, but few of these have equalled, let alone surpassed, the results of saphenous vein grafts. DeBakey et al. (1973) quote a 70 per cent 5-year patency with Dacron prostheses in a large series, as does Reichle (1978). However, this has not been the general experience, and only 50 per cent of Dacron prostheses remained patent in the series reported by Stephen et al. (1977). Veith et al. (1978) found comparable patency rates between PTFE and autogenous vein grafts after 14 months, but the late results of the former have been disappointing. Interestingly, combined Dacron–vein grafts have a 71 per cent 5-year patency in a short series of 29 cases reported by Friedmann et al. (1976). These grafts may be useful if the saphenous veins are inadequate.

We have reported a low 5-year mortality of 14·6 per cent whereas reports from others have quoted considerably higher mortality rates of 25 per cent, 38 per cent and 48 per cent respectively at 5 years (DeWeese and Robb, 1977; Myhre, 1977; Alinaji et al., 1978).

The best results are obtained by using large calibre veins above the knee joint; fortunately, 75–80 per cent of cases are suitable for this purpose. Regrettably, results are much less satisfactory with below-knee grafts and we do not agree that implantation is beneficial and should be routine (Sabga et al., 1968). In our experience the disadvantage of the graft kinking across the knee joint outweighs the risk of progressive distal popliteal occlusive disease. Perhaps a suitable compromise should be graft insertion at the knee joint. Like Darling et al. (1967), we feel that graft failure is usually related to progressive distal atherosclerosis; however, we have occasionally seen gangrene develop in limbs where the graft remained pulsatile. Serial arteriography indicated progressive occlusion of run-off arteries. Although not routine, regular arteriograms (Dhall and Mayor, 1978) or ultrasonics (Taylor and Fox, 1977) may predict potential graft failure.

Our limb salvage rate (77 per cent) compares favourably with other series and we re-emphasize that a temporarily functioning graft may still prevent the loss of a limb even after the graft occludes. Five-year patency rates of grafts inserted for limb salvage were at least 60 per cent in series reported by O'Donnell et al. (1977) and Logerfo et al. (1977), but it is not clear from their papers whether the term 'limb salvage' is only applied to patients with advanced ischaemia.

The major problem in management is how to maintain graft patency and prevent distal progressive occlusive disease. We can draw no valid conclusions on the role of anticoagulants or sympathectomy in our series and other reports vary (Buda et al., 1976; Cutler et al., 1976). Studies with antiplatelet drugs may give hope for the future. However, we agree that complete cessation of smoking is mandatory (Myers et al., 1978) and research should continue to be guided towards elucidating the basic mechanisms of atherosclerosis and blood clotting and the prevention of complications in these patients (Harris et al., 1978).

Acknowledgements

We acknowledge the help of all members of the hospital staff who contributed to these operations over the years and of the general practitioners who assisted in the follow-up of patients. Our thanks to Miss P. Cole for secretarial assistance.

Fine needle catheter jejunostomy—an assessment of a new method of nutritional support after major gastrointestinal surgery

C. K. YEUNG, G. A. YOUNG, A. F. HACKETT AND G. L. HILL*

SUMMARY

The results of our experience with the technique of fine needle catheter jejunostomy and early postoperative feeding through the catheter over a 12-month period are presented. Of the 43 patients who had the catheter inserted, 27 (63 per cent) completed a course of feeding with an elemental diet without complications, 3 (7 per cent) were not fed for different reasons and 13 (30 per cent) developed complications that led to temporary or permanent cessation of the feeding. One patient in this group died of inhalation pneumonia.

The voluntary food intake of 12 of the patients who were fed by jejunostomy after major colorectal surgery was assessed daily for 2 weeks after operation and compared with that of 12 control patients who did not have nutritional support. No significant difference in voluntary food intake was found between the two groups.

The changes in body composition and plasma proteins and the clinical outcome of 20 of the patients fed by jejunostomy after major colorectal surgery were also compared with those of 20 matched controls. Body weight and lean body mass (as assessed by total body potassium and arm muscle circumference) and plasma prealbumin fell significantly in the control patients but not in those fed by jejunostomy. However, plasma transferrin decreased in both groups and there was no significant difference in clinical outcome in terms of complication rate or duration of postoperative hospital stay.

The study would suggest that this technique of jejunostomy feeding should be reserved for selected cases where it may prove to be of real value, rather than being used routinely.

THE provision of nutritional support after major surgery either by intravenous nutrition (Collins et al., 1978) or by administration of an elemental diet through a nasogastric tube (Sagar et al., 1979) can prevent postoperative nitrogen loss and appears to have some clinical benefits. However, the routine administration of intravenous nutrition after surgery is expensive and difficult in practice. Nasogastric feeding, though cheaper and relatively simpler, may not be acceptable to many patients for more than a few days. A jejunostomy performed at the conclusion of the main operation provides an alternative route of administering the nutrients, and in recent years the relatively simple technique of fine needle catheter jejunostomy has been described and favourable results reported (Delany and Garvey, 1973; Delany et al., 1977).

This present prospective study was carried out with a view to assessing: (*a*) the safety and simplicity of the technique; (*b*) the effect of feeding through the jejunostomy on postoperative voluntary food intake; (*c*) the effect on nutritional status in terms of lean body mass and plasma proteins; and (*d*) whether there are any clinical benefits.

Patients and methods

The study was carried out on patients admitted to the University Department of Surgery at Leeds between January 1978 and January 1979 for elective major colorectal or gastro-oesophageal surgery. The patients were interviewed on admission and informed consent to the study was obtained.

Jejunostomy technique

Forty-three patients had a fine needle catheter jejunostomy inserted at the time of surgery using the method described by Delany et al. (1977). Essentially this consists of creating a submucosal tunnel about 10 cm long in a loop of proximal jejunum, using a 5·1-cm stainless-steel needle with an internal diameter of 1·5 mm (Bard-I-Cath, CR International Ltd), and threading a fine plastic catheter, 40 cm long with an external diameter of 1·5 mm and an internal diameter of 1·0 mm (Vigon Umbilical Catheter, Vigon UK Ltd, Middlesex), through it into the jejunum. The needle is withdrawn over the catheter and a purse-string suture inserted in the jejunal wall around the catheter. Using the same needle the catheter is threaded through the anterior abdominal wall; finally the loop of jejunum is attached to the parietal peritoneum and the catheter fixed to the skin.

Management of jejunostomy feeding

Postoperatively the patients were assessed daily to determine when feeding through the jejunostomy catheter could be started. In general, feeding was initiated as soon as was practical (usually within 48–72 h after operation), provided that the general condition of the patient was satisfactory and abdominal distension and vomiting were absent. Just before feeding, 5 ml of Gastrografin were injected into the jejunostomy catheter and an abdominal X-ray taken to confirm the position of the catheter in the bowel lumen.

An elemental diet (Flexical, Mead Johnson Laboratories) was used for the jejunostomy feeding: 1000 ml of the reconstituted diet contain 22·5 g of protein equivalent, 152·5 g of carbohydrate and 34·0 g of fat and provide 1000 kcal (4·2 MJ) of energy in addition to essential minerals and vitamins. At 'normal' strength the diet has an osmolality of 550 mmol/kg water. However, when feeding was first started, a half-strength diet (½ kcal/ml) was given at the rate of 30 ml/h for the first 24 h. If this was tolerated, the volume and strength were gradually increased until a full regimen of 2000–3500 kcal/day was achieved, depending on the size and estimated requirements of the patient. A McGaw N7922 volumetric infusion pump (Imed Corporation, San Diego, California) was used to deliver the diet.

Assessment of voluntary food intake

To examine the effect of jejunostomy feeding on oral intake we studied the voluntary food intake (VFI) in 12 patients who were fed by jejunostomy after major colorectal surgery and in 12 control patients who had similar surgery but were not given any nutritional support. The daily VFI in terms of energy was assessed over a 2-week period after operation using the weighed inventory method (Marr, 1971; Hackett et al., 1979) and a standard food table (McCance and Widdowson, 1973).

---

* University Department of Surgery and Renal Research Unit, The General Infirmary, Leeds.

The home VFI was assessed by a dietary history technique similar to that described by Burke (1947), and the daily postoperative VFI was expressed as a percentage of the home intake, since it has previously been shown that a close correlation exists between the maximum postoperative VFI attained and the home VFI (Hackett et al., 1979).

Assessment of nutritional status
Twenty of the 43 patients who had the jejunostomy inserted were matched in a prospective way for sex, age, body weight, preoperative weight loss (as a percentage of recalled pre-illness weight), diagnosis and extent of surgery (all had colorectal surgery) with 20 control patients who were not given postoperative nutritional support. Both groups of patients were otherwise managed in a similar manner, and were allowed to start eating or drinking when their clinical progress permitted. The effect of jejunostomy feeding on nutritional status and clinical outcome was studied.

Body composition measurements: All the patients had the following measurements taken just before surgery and repeated at 2 weeks after surgery: (*a*) body weight; (*b*) body fat, as calculated from measurement of the thickness of the biceps, triceps and subscapular skinfolds, using the method of Durnin and Womersley (1974); (*c*) arm muscle circumference (AMC), derived from the measurement of the mid-arm circumference (MAC) and the triceps skinfold (t) where $AMC = MAC - \pi t$; (*d*) total body potassium (TBK), determined by measuring the activity of the naturally occurring radioisotope ^{40}K using a whole body counter.

Plasma protein measurements: Venous blood samples were taken (between 0800 h and 1000 h) before operation and 14 days after operation in both groups of patients. Normal values for plasma proteins were obtained from members of hospital staff or patients with insignificant problems. Plasma transferrin and prealbumin (markers of malnutrition) and α_1-antichymotrypsin (an acute phase protein) were determined by radial immunodiffusion technique (Young et al., 1978).

Statistics
The mean changes in the various parameters of body composition for the two groups of patients were calculated, together with the 95 per cent confidence limits.

For analysis of the postoperative voluntary food intake and plasma protein levels, Student's t test was used.

Results

Clinical material

Over the 12-month study period 43 patients had a needle catheter jejunostomy inserted while undergoing major gastrointestinal surgery. The diagnosis and extent of surgery performed in these patients are shown in *Table I*. Five patients underwent gastro-oesophageal resection and 38 underwent colorectal resection.

Table I: DIAGNOSIS AND EXTENT OF SURGERY IN PATIENTS STUDIED

	No. of patients
Total gastrectomy (carcinoma of stomach)	3
Gastro-oesophagectomy (carcinoma gastro-oesophageal junction)	2
Abdominoperineal excision of rectum (10 carcinoma of rectum + 1 ulcerative colitis)	11
Proctocolectomy (ulcerative colitis)	1
Subtotal colectomy (2 carcinoma of colon + 2 ulcerative colitis)	4
Anterior resection (carcinoma of rectum)	10
Hartman's resection (carcinoma rectosigmoid junction)	2
Hemicolectomy (carcinoma of colon)	4
Sigmoid colectomy (carcinoma of colon)	6
Total	43

Outcome of jejunostomy feeding and complications

The outcome of feeding through the catheter jejunostomy in the 43 patients is shown in *Table II*. Three patients had a catheter inserted but were not fed postoperatively. One sustained a massive pulmonary embolus on the second postoperative day and died 2 days later. The second patient had severe respiratory problems in the early postoperative period, requiring a period of positive pressure ventilation in the intensive care unit, as well as a severe ileus which precluded feeding through the jejunostomy. In the third patient the catheter was shown to be lying outside the bowel on routine X-ray with Gastrografin. The catheter was withdrawn and the patient suffered no ill effect.

Table II: OUTCOME OF JEJUNOSTOMY FEEDING IN 43 PATIENTS

	No. of patients
Patients who had jejunostomy catheter but not fed (includes 1 death due to pulmonary embolus)	3
Feeding discontinued completely because of vomiting, abdominal distension or pain (includes 2 deaths)	8
Feeding discontinued temporarily because of nausea, vomiting, abdominal distension, but resumed after short rest	4
Feeding discontinued because catheter pulled out accidentally	1
Course of feeding completed as planned	27
Total	43

Feeding was discontinued in 6 patients because of vomiting, abdominal distension and/or abdominal pain that was thought to be related to the jejunostomy feeding. Two other patients died in the course of feeding. One of these was a 75-year-old woman who, 5 days after anterior resection of a rectal carcinoma, became confused and inhaled vomit during the night; in spite of intensive treatment she died 10 days later of her chest complications. The second patient was another 75-year-old woman who underwent abdominoperineal excision of the rectum for carcinoma. She also was rather confused postoperatively but seemed satisfactory in every other respect. Four days after surgery she suddenly vomited during the night and sustained a cardiac arrest shortly afterwards. The precise cause of death in this second case was not known as permission for a post-mortem examination was refused, and inhalation of vomit as a primary cause remained a possibility.

Four patients developed vomiting and/or abdominal distension in the early stages of feeding but these complications settled when feeding was discontinued for a short period (2–3 days) and it was possible to resume feeding up to the fourteenth postoperative day in these patients.

In one patient the jejunostomy catheter was pulled out accidentally 10 days after gastro-oesophagectomy and feeding was therefore discontinued. Twenty-seven patients completed a planned course of feeding until the second week after operation.

In all but one patient no difficulty was encountered in removing the catheter when this was no longer required. One patient had to be sedated and forceful traction was required to withdraw the catheter; when it was removed the end was found to be tied in a knot.

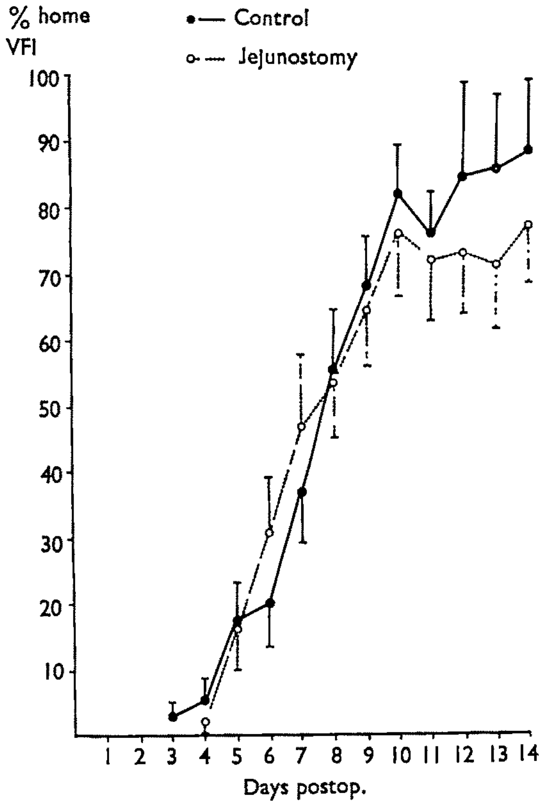

Fig. 1. Voluntary food intake (VFI) in the two groups of patients, expressed as a percentage of the home voluntary food intake, during the first 14 days after operation (mean ± s.e. mean).

One patient developed minor sepsis at the site of the catheter after its removal, but this settled without any active treatment. None of the patients developed a fistula.

Calories achieved

In those 27 patients who completed the course of postoperative feeding as planned, feeding was initiated on average 3·0 ± 1·8 days (mean ± 1 s.d.) after surgery and lasted for a mean period of 10·9 ± 2·7 days. Over this period the average intake through the jejunostomy catheter was 1692 ± 270 kcal/day (29·9 ± 8·2 kcal kg body weight^{-1} day^{-1}). There was a significant correlation between the average daily energy intake through the jejunostomy and the duration of feeding ($r = 0{\cdot}63$, $P < 0{\cdot}01$).

Effects of jejunostomy feeding on voluntary food intake

Fig. 1 shows the mean daily voluntary food intake (expressed as a percentage of the home intake before surgery) of the subgroup of 12 patients fed by jejunostomy and that of the group of 12 control patients. Both groups underwent comparable colorectal surgery. It can be seen that in both groups of patients the VFI increased gradually until it reached a peak round about the tenth postoperative day after which it remained relatively constant. There was no significant difference in the mean food intake between the two groups for any of the 14 postoperative days ($P > 0{\cdot}05$).

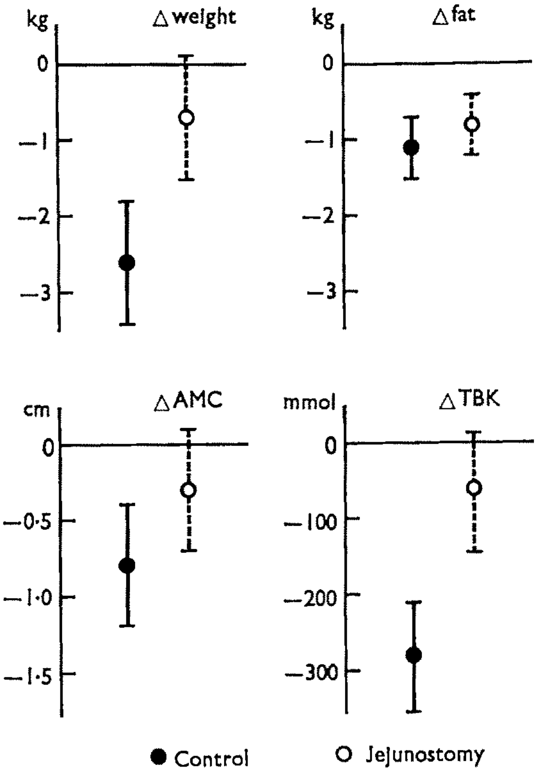

Fig. 2. Mean changes (with 95 per cent confidence limits) in body weight, body fat, arm muscle circumference (AMC) and total body potassium (TBK) in the two groups of patients.

Table III: MATCHING DATA IN THE TWO GROUPS OF PATIENTS IN WHOM BODY COMPOSITION AND PLASMA PROTEIN MEASUREMENTS WERE MADE

	Control	Jejunostomy
Male : Female	10 : 10	10 : 10
Age (yr)	62·8 ± 9·9	64·6 ± 9·4
Height (cm)	164·3 ± 8·7	163·1 ± 10·7
Body weight (kg)	62·1 ± 13·7	58·2 ± 12·8
Preop. weight loss (%)	8·7 ± 7·2	8·1 ± 7 8

Values are mean ± 1 s.d.

Effect on body composition

Table III shows the sex distribution, mean age, height, body weight and percentage weight loss in the subgroup of 20 patients whose body composition was measured, compared to those of 20 control patients. All these parameters were very similar in both groups. The diagnosis and extent of surgery were also closely matched in the two groups.

Fig. 2 shows the mean changes (with 95 per cent confidence limits) in body weight, body fat, arm muscle circumference (AMC) and total body potassium (TBK) in the two groups over the 2-week period. There was a mean loss of 2·5 kg in body weight in the control patients, but no significant loss in those receiving the elemental diet. There was a smaller but significant loss of body fat (1·1 and 0·8 kg respectively) in both groups. AMC was decreased significantly in

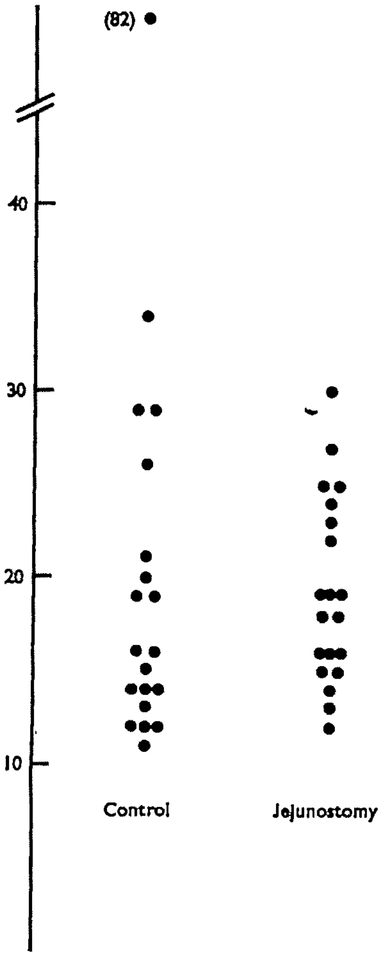

Fig. 3. Duration of hospital stay (in days) after surgery in the two groups of patients.

the control group, but not in the elemental diet group. Similarly, there was a significant loss in TBK (285 mmol) in the control group but not in the elemental diet group.

These results show that the loss of body weight and lean body mass was prevented in those patients who received the elemental diet through the jejunostomy.

Effect on plasma proteins

The mean concentrations of proteins in preoperative and postoperative plasma samples for each of the two groups of patients are compared with normal values in *Table IV*. Mean values for transferrin and prealbumin before surgery were not significantly different from normal. Lowest concentrations of these proteins occurred in patients with the greatest preoperative weight loss.

Two weeks after surgery mean plasma transferrin and prealbumin in the control group were lower than normal. However, in the jejunostomy group the mean prealbumin was restored to the preoperative concentration, and was decreased only in 6 patients (4 who had less than 65 per cent of the mean intake of elemental diet, 1 with sepsis, and 1 with unexplained pyrexia).

Table IV: MEAN VALUES (±s.e. mean) FOR PLASMA TRANSFERRIN, PREALBUMIN AND α_1-ANTICHYMOTRYPSIN IN NORMAL INDIVIDUALS AND IN PATIENTS BEFORE SURGERY AND 2 WEEKS AFTER SURGERY

Group	Trans. (mg/100 ml)	Prealb. (mg/100 ml)	α_1-Antichy. (mg/100 ml)
Normals ($n = 12$)	285±11	28·5±1·2	44±3
Controls ($n = 20$)			
Preop.	279±11	23·9±1·7	76±4†
Postop.	226±9* −53‡	20·4±1·5* −3·5‡	114±6† +38‡
Jejunostomy ($n = 20$)			
Preop.	264±13	24·4±1·7	74±4†
Postop.	226±14* −41‡	24·2±1·7 −0·2	110±6† +36‡

Trans., Transferrin; Prealb., prealbumin; α_1-Antichy., α_1-antichymotrypsin.
* Mean values lower than normal, $P<0{\cdot}005$.
† Mean values higher than normal, $P<0{\cdot}001$.
‡ Mean changes significantly greater than zero, $P<0{\cdot}01$.

Table V: POSTOPERATIVE COMPLICATIONS IN 20 CONTROL PATIENTS AND 20 PATIENTS FED BY JEJUNOSTOMY

	Control ($n = 6$)	Jejunostomy ($n = 7$)
Anastomotic leak+local abscess	1	1
Abdominal wound infection	1	—
Ileus	—	3
Chest infection	1	—
Urinary tract infection	2	3
Urinary retention	2	1
Cardiac failure	1	—
Cerebrovascular accident	1	—
Total complications	9	8

In contrast, the mean transferrin level was lower than normal, as for controls.

The mean concentration of α_1-antichymotrypsin was above normal in both groups. Following the 2-week period, there were comparable increases in the mean values for both groups, suggesting a similar response to sepsis and trauma.

Clinical effects

Fig. 3 shows the duration of stay in hospital after surgery (in days) in the two groups of patients. One patient in the control group had a cerebrovascular accident and stayed in hospital for 82 days, otherwise, the duration of stay in hospital was similar in both groups. Eight patients in the control group and 3 patients in the elemental diet group went home by the fourteenth postoperative day. It is conceivable that the presence of the jejunostomy may have delayed the discharge of patients in this group by a few days though every effort was made at the time of the study to prevent this from happening. However, since the feeding was terminated at 2 weeks, this cannot be held responsible for delay in hospital discharges beyond the 2-week period.

Table V shows the main complications that occurred in the two groups of patients. Though the number of complications was roughly equal—9 complications in 6 control patients and 8 complications in 7 patients fed by jejunostomy—the type of complication differed. In particular, there were 3 patients in the group fed by jejunostomy who had a prolonged ileus (>6 days), while this complication was not seen in the control group.

Discussion

This study shows that the actual technique of needle catheter jejunostomy is simple and safe to perform. Of the 43 catheters inserted, one was pulled out accidentally during feeding and in another patient the catheter became dislodged from the bowel, but this was detected on routine X-ray with Gastrografin. There were no instances of leakage of the nutrient solution into the peritoneal cavity, fistula formation or intestinal obstruction due to adhesions at the jejunostomy catheter site, and none of our patients required reoperation for complications resulting from the catheter.

The inherent safety of the technique is supported by other authors. Page et al. (1978) report 4000 patient-days of catheter jejunostomy feeding in 181 patients with only 2 major complications (1·1 per cent) requiring reoperation. Delany et al. (1977), in a series of 115 patients, had 4 cases in which the catheter became dislodged and 2 of these came to surgery. In the latter cases the catheter was secured to the bowel wall but the bowel was not sutured to the parietal peritoneum. It seems important, therefore, to suture the bowel to the peritoneum in all cases to prevent dislodgement of the catheter and subsequent instillation of the nutrient solution into the peritoneal cavity.

Though the actual technique of needle catheter jejunostomy is simple and relatively safe, the delivery of the elemental diet through the catheter requires great care as complications are not uncommon and may in certain instances be serious. In our 43 patients, 27 (63 per cent) completed a course of feeding without interruption, but in 12 (28 per cent) the feeding was either temporarily or permanently stopped because of complications which seemed to be related to the feeding. The commonest cause was abdominal distension and vomiting. Two patients died during the course of feeding in this series: both were elderly female patients who were confused postoperatively. One died of aspiration pneumonia, but the cause of death in the second one was uncertain though she was reported as having vomited before sustaining a cardiac arrest. Both these patients vomited during the night and the vomitus, described as 'clear bile', did not appear to contain the elemental diet. Intragastric administration of elemental diets has been shown to cause delay in gastric emptying (Bury and Jambunathan, 1974), but the effect of giving the diet intrajejunally on gastric motility and gastric and biliary secretion is not known, though there seems to be little effect on pancreatic secretion (Ragins et al., 1973; Kelly and Nahrwold, 1976). It may be that some of the problems with abdominal distension and vomiting in our patients were due to our attempt at starting the feeding through the jejunostomy catheter too early.

It was interesting to find that the administration of the elemental diet via the jejunostomy catheter did not depress oral food intake, as compared with control patients who did not receive supplementary feeding by jejunostomy. The net energy intake (and protein intake) was therefore significantly increased (more than doubled) in those patients with the jejunostomy feeding, and the nutritional benefits are reflected in maintenance of body weight and of lean body mass as assessed by total body potassium and arm muscle circumference.

We have previously found that clinical improvement has been associated with increases in visceral proteins (Young et al., 1979), and these are intimately involved with host defence and survival. It is therefore encouraging that plasma prealbumin, with a half-life of 2 days, was restored to the preoperative concentration, although transferrin, with a half-life of 8 days, remained low. This suggests that if more calories and nitrogen had been supplied by the jejunostomy feeding, these 'visceral proteins' may have been increased. Evidence for this is suggested by the correlation between the changes in plasma prealbumin concentration and the total amount of elemental diet ($r = 0{\cdot}64$, $P < 0{\cdot}01$).

These changes in plasma proteins are compatible with the clinical observations, notably that there was no advantage in terms of duration of hospital stay after surgery and complication rate in those patients fed by jejunostomy as compared with controls. Our results differ from those of the study reported by Sagar et al. (1979) in which it was shown that administration of an elemental diet into the upper small intestine through a double lumen tube during the first week after surgery is associated with fewer postoperative complications and a shorter stay in hospital in patients undergoing major gastrointestinal surgery.

Our results indicate that there is little justification in the routine use of this technique of postoperative feeding, at least after colorectal surgery. It should be reserved perhaps for selected cases—patients who present for major surgery after significant preoperative weight loss and in whom further weight loss in the postoperative period may be detrimental for their recovery; or patients in whom the surgeon anticipates complications and/or delay in taking nutrients orally. We have found the technique particularly useful in patients undergoing gastro-oesophageal surgery as it is our routine to withhold oral intake in these patients until the integrity of the anastomosis has been checked with a Gastrografin swallow about 10 days after operation. If a leak is demonstrated, the patient can be maintained in a good nutritional state through the jejunostomy feeding while waiting for the leak to close spontaneously.

Acknowledgements

The authors would like to thank Dr L. Burkinshaw, Dr C. B. Oxby and other members of the Department of Medical Physics, the technical staff of the Renal Research Unit, Professor D. Johnston, Mr P. Lyndon, Mr P. Armitstead, Mr J. Macfie, Mr A. Bakran and Mr M. Odell of the University Department of Surgery, and the nursing staff on Wards 27 and 28, The General Infirmary, Leeds, for their help and encouragement. This study was made possible by a grant from Mead Johnson Laboratories.

Lesser curve superficial seromyotomy—an operation for chronic duodenal ulcer

THOMAS V. TAYLOR*

SUMMARY
Lesser curve superficial seromyotomy has been investigated in the dog and in man. The anatomical basis for the operation, which produces an easily performed denervation of the parietal cell mass, is discussed. Acid studies in the dog confirmed that the operation was capable of producing secretory inhibition in keeping with vagotomy of the parietal cell area.

A consecutive series of 25 patients with chronic duodenal ulcer has been treated by lesser curve myotomy without a drainage procedure. The operation has the advantages of being easily performed and the risk of damage to the nerve of Latarjet or of ischaemic necrosis of the lesser curvature is obviated. In 20 insulin tests performed within the first month postoperatively all patients have been negative within the first 75 min and there were 4 late positive responses. Early clinical results have been encouraging, there has been no dumping or diarrhoea and all patients are well. It is suggested that further investigation of lesser curve myotomy is warranted.

HIGHLY selective vagotomy has steadily become established in the treatment of peptic ulceration since it was first performed without a drainage procedure in man (Amdrup and Jensen, 1970; Johnston and Wilkinson, 1970). By 1975 Johnston reported only 17 deaths following 5539 operations carried out in Britain, Scandinavia and the United States, an operative mortality of 0·3 per cent. The rate of recurrent ulceration, in those series with longer follow-up, has been reported at 4·3 per cent by Goligher et al. (1978) and Dorricott et al. (1978) and 5·4 per cent by Stoddard et al. (1978), incidences similar to that following truncal vagotomy and drainage. However, highly selective vagotomy is not without its disadvantages, namely that the operation is tedious and time-consuming to perform, damage to the nerve of Latarjet may produce gastric stasis and there is a small risk of ischaemic necrosis which, when it does occur, is not uncommonly fatal (Newcombe, 1973; Hall et al., 1974; Wyllie, 1974; Halvorsen, 1975).

In the Edinburgh area between 1976 and 1978, 584 elective operations were carried out for duodenal ulceration; 110 of these were highly selective vagotomies and 474 vagotomy and drainage procedures. Thus, highly selective vagotomy has been slow to gain widespread acceptance, accounting for only 18·8 per cent of operations for duodenal ulceration performed in the Edinburgh area. In this study the aim has been to develop an operation which denervates the parietal cell mass, which can be more easily and expeditiously performed and which carries neither risk of damage to the nerve of Latarjet nor of ischaemic necrosis of the lesser curvature.

Anatomical considerations

Considering the anatomy of the vagus nerve, Latarjet (1922), McCrea (1924) and Mitchell (1940) all emphasized that the gastric branches of the nerve of Latarjet, or the greater anterior and posterior gastric nerves, have no predilection to run with the vessels along the walls of the stomach. Mitchell (1940) stated that the nerves can be traced for some distance beneath the serous coat before they sink into the stomach musculature. The present author's anatomical observations have confirmed that these nerves always run superficial to and more obliquely than those major blood vessels leaving the left and right gastric arteries and running along the walls of the stomach from the lesser curve aspect. Any nerves accompanying the vessels are usually sympathetic, a parasympathetic nerve crossing a vessel does so superficially.

Lesser curve myotomy

Based upon these anatomical observations, a method of denervating the parietal cell mass by gastric lesser curve superficial seromyotomy has been devised. In this operation the vagal branches are divided as they run with the serosa along the lesser curvature. The oblique and superficial circular muscle fibres are divided along with the serosa, permitting wide separation of the nerves. Most of the major vessels running along the lesser curvature are left intact, the serosa running superficial to them is divided and the myotomy can be continuous beneath. The nerves of Latarjet need not be identified; they are not at risk of damage during the operation and the integrity of the antral and pyloric innervation is maintained.

The extent of the myotomy running along the lesser curvature from the oesophagogastric junction to the antrocorpus junction is shown in *Fig.* 1. This diagram illustrates the separation of the nerves which must occur along the myotomized segment and the integrity of those two or three major vessels proximal to the crow's foot.

Materials, patients and methods

Animal experiments

Experiments were first performed in the dog. A gastric cannula was inserted and pentagastrin infusions were carried out on three separate occasions in 4 dogs. An initial dose of 0·375 $\mu g\ kg^{-1}\ h^{-1}$ was doubled at half-hourly intervals until a dose of 6 $\mu g\ kg^{-1}\ h^{-1}$ was infused. Three separate insulin tests were performed using 0·2 units/kg i.v. Lesser curve myotomy was then carried out and three further pentagastrin and insulin tests were performed more than 1 month postoperatively. Acid output was determined by titration to pH 7·0 using an autotitrator.

Lesser curve myotomy in man

Twenty-five procedures have been performed in man between February 1978 and February 1979. There were 15 males and 10 females aged 42·5 ± 13·5 s.d. years. In each case the diagnosis was made clinically, radiologically at laparotomy and usually by endoscopy. The series is consecutive apart from those patients treated as emergencies with either perforation or haemorrhage. In 3 cases a degree of pyloric stenosis was

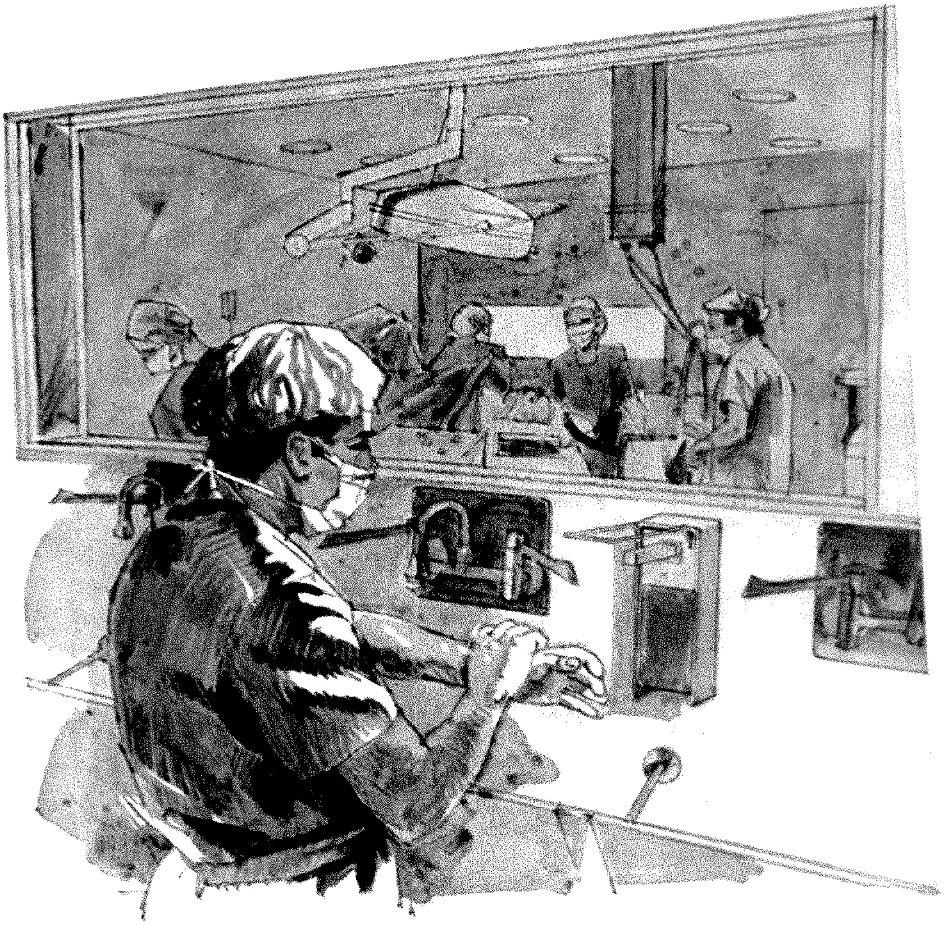
present: in 2 the pylorus was stretched through a gastrotomy and myotomy of the lesser curve was performed and in the third the duodenum split on stretching and pyloroplasty was carried out, the patient then being excluded from the series.

Operative technique

The abdomen was opened through an upper midline incision, the primary pathology and absence of associated pathology were confirmed and the pylorus was assessed for stenosis. The anterior and posterior vagal trunks were identified and mobilized and slings were individually placed around these. The lower 6–7 cm of oesophagus were cleared of any fine strands of vagus. The anterior nerve of Latarjet was first mobilized by dividing the neurovascular bundle which runs across the oesophagogastric junction. These are the only vessels which invariably require division, after which the nerve of Latarjet can be retracted medially and the anterior gastric wall is exposed for commencement of the myotomy.

The serosa and superficial layers of oblique and circular muscle were next incised parallel to the lesser curvature from the oesophagogastric junction down the incisura. The incision in the serosa was initially made by diathermy and then the muscle fibres were divided with scissors. The divided muscle fibres retract widely following gentle displacement with a small pledget. Occasional deeper circular muscle fibres remained intact and then a little bleeding was encountered. The divided vagal branches which run in the superficial serosa at the site of the myotomy became separated by about 1 cm. Where large gastric vessels ran from the left gastric artery and vein to the anterior and posterior walls of the stomach these were in the main carefully preserved, but the myotomy was extended to the tissues lying directly adjacent to these vessels.

Hibiscrub/Hibiclens
chlorhexidine gluconate
Closest to the ideal skin cleanser



- Wide-range antimicrobial activity
- Rapid and persistent microbicide
- Well tolerated
- As elegant as it is effective

*Hibiscrub is the trademark for a solution containing chlorhexidine gluconate in all countries (Hibiclens, in USA and Australia).

SHOCK

Trasylol®
aprotinin

increases the chances of survival in traumatic-haemorrhagic shock

The results of a large German field study1): Marked reduction of mortality when Trasylol was applied early. Precise clinical investigations in 70 shock patients by an Australian double-blind study2) provided an explanation and further proof for the effectiveness of Trasylol in shock: With Trasylol development of post-traumatic respiratory insufficiency (shocklung) was less frequent.

®Registered Trade mark of Bayer Germany

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*

Should a nerve obliquely cross a vessel along the line of myotomy this can usually be seen and the vessel sacrificed. Where a decision was made to divide vessels 'liga clips' were used, but always at least two large vascular bundles were left intact, obviating any risk of ischaemic necrosis of the lesser curvature.

The posterior myotomy was begun from below at the level of the incisura. The avascular plane between the left and right gastric vessels was opened and, in addition, a window was formed in the greater omentum preserving the gastroepiploic arch. The author has found it most convenient to begin the myotomy through the lesser omental opening and to complete it by rotating the stomach medially and extending the myotomy proximally and laterally below the oesophagogastric junction.

Postoperatively a nasogastric tube was used for 48 h after which oral fluids were commenced leading to a light diet by the fourth postoperative day.

Gastric function tests

Pentagastrin stimulation tests were performed preoperatively in all patients. Fasting juice was aspirated and basal secretions collected for 1 h before intramuscular injection of pentagastrin (Peptavlon) 6 μg/kg. Four further 15-min collections of continuously aspirated secretions were carried out. Acid concentration was measured by titration with one-tenth normal sodium hydroxide to pH 7·0 using an autotitrator. Insulin tests have been performed within 1 month in 20 patients and have been repeated in those who have attained 6-month follow-up. These tests have been carried out by an infusion test (Carter et al., 1973) using a dose of 0·04 units $kg^{-1} h^{-1}$ and employing the criteria of Hollander (1946).

Follow-up

Patients were reviewed at 1, 3, 6 and 12 months. Questions were specifically asked from a proforma regarding pain, dyspeptic symptoms, dumping, diarrhoea or other problems. The patients were then graded I–IV on a Visick scale. The follow-up varied in length from 3 months to 1 year.

Results

Animal study

The mean acid output in 4 dogs together with the standard deviation in response to graded doses of pentagastrin is shown in *Fig.* 2. The reduction in acid output shown postoperatively, with its characteristic shift to the right, is in keeping with the observations on acid output after truncal vagotomy in the dog described by Emas and Grossman (1967). The effect of insulin (0·2 units/kg i.v.) on acid output is shown in *Fig.* 3. Three of the dogs showed no rise in acid secretion in response to insulin but 1 showed a late response of very small magnitude.

Human study

There has been no mortality, minimal morbidity and the clinical results have been good, although follow-up is short. Ulcer pain and acid regurgitation have been completely relieved to date. The inpatient stay ranged from 6 to 22 days with a mean of 9·4 ± 3·65 s.d. Normal diet had been resumed by the first review at 1 month in all patients, and bowel habits had remained or returned to normal at this time. There has been no dumping and no postvagotomy diarrhoea.

One patient had symptoms of gastric stasis which spontaneously resolved by 1 month. Wound infection occurred in 3 patients and chest infection in 5. There has been one complication directly attributable to the procedure: the mucosa was perforated in a 48-year-old male who underwent reoperation on the fourth postoperative day. A small hole in the anterior lesser curvature was oversewn and was considered to be due to a diathermy burn. This hazard is avoidable and need not be associated with the procedure. Diathermy is no longer used to divide the muscle fibres and its use is confined to incising and occluding small vessels on the serosa.

Follow-up at 3 months in 20 patients revealed them all to be Visick grade I and those 9 patients reviewed at 6 months and the 3 seen at 1 year remained symptom-free. There has been a total absence of recurrent ulcer symptoms.

Gastric secretion

In 20 patients the mean basal acid output per hour was reduced from 5·0 ± 4·3 s.d. mmol to 0·77 ± 0·66 s.d. mmol in the early postoperative period, a mean reduction of 85 per cent. Using Hollander's criteria for assessment of the insulin tests all patients were negative in the first 75 min after commencement of insulin infusion. Four patients had a late rise in acid concentration of greater than 20 mmol/l between 75 and 120 min after insulin. Those secretory results so far obtained at 6 months after operation show a tendency for reversal from negative to positive. The magnitude of this reversal in terms of acid output appears small and in keeping with that reported by Lyndon et al. (1975) after highly selective vagotomy.

Gastric emptying, both liquid and solid phase, with measurements of early emptying, is being assessed. A double isotope scanning technique for simultaneous study of liquid and solid components of a cornflakes, sugar and milk meal is being used (Heading et al., 1976). This will form the basis of a later study, but there is no evidence of either gastric hold up following myotomy or of rapid early emptying.

Discussion

The animal experiments formed the basis for investigation in man. The pattern of acid secretory inhibition produced by myotomy in response to stimulation by pentagastrin is similar to that in response to histamine and gastrin in dogs after truncal vagotomy (Emas and Grossman, 1967). The secretory output in response to insulin stimulation was similar to that after truncal vagotomy in 3 dogs (Emas and Grossman, 1967), and 1 dog showed a slight rise in acid secretion. Griffiths and Harkins (1957) described a small acid secretory response in 7 of 10 dogs in their experimental study of partial gastric vagotomy, the study which formed the basis of highly selective vagotomy as we know it. The animal experiments described in the present study suggest that the acid secretory inhibition achieved by lesser curve myotomy is comparable with that produced by conventional highly selective vagotomy, at least in the short term.

Despite the physiological advantages of confining vagotomy to the parietal cell area of the stomach, vagotomy and drainage remains the most commonly performed operation for duodenal ulcer. The major objection to highly selective vagotomy raised by surgeons is that the operation is tedious and time-consuming, as every nerve and blood vessel passing on to the lesser curve of the stomach, above the incisura, has to be ligated and divided. Favourable reports of highly selective vagotomy in consecutive series have come from Humphrey et al. (1972), Amdrup et al. (1974), Hallenbeck et al. (1976), Holst-Christensen et al. (1977) and Goligher et al. (1978) and from prospective clinical trials comparing highly selective with other forms of vagotomy (Kennedy et al., 1975; Kronborg and Masden, 1975; Dorricott et al., 1978).

The main advantage of lesser curve myotomy is that it produces a highly selective vagotomy in an expeditiously and easily performed manner. There should be neither risk of damage to the nerve of Latarjet, which need not be identified, nor of ischaemic necrosis of the lesser curvature. Ramstedt in 1912 introduced pyloromyotomy, an operation which carries a mortality of only 0·5 per cent in the neonate (Benson and Lloyd, 1964). Heller (1913) described oesophagomyotomy, which has also stood the test of time and been shown to be intrinsically safe. In lesser curve myotomy the area between oesophagus and antrum is myotomized and there is no reason to believe that myotomy in this situation should be associated with any greater morbidity than has been reported in the other two adjacent sites over the past 65 years. The one complication directly attributable to the operation, that of gastric perforation, was considered to be due to a diathermy burn. Initially the muscle fibres were divided by diathermy; the use of diathermy is now confined to the incision in the serosa and the coagulation of small vessels running along the serosal surface, the muscle fibres are divided by blunt-ended dissecting scissors. The integrity of the mucosa is checked at the end of the operation by introducing air into the stomach and it is currently considered that the risk of perforation is entirely avoidable.

Two major anatomical considerations are fundamental to the success of this procedure. First, that all vagal branches passing to the parietal cell area are divided and, secondly, that the divided nerves do not regenerate. The anatomical descriptions of Latarjet (1922), McCrea (1924) and Mitchell (1940) have been confirmed by our own observations that the branches of the nerves of Latarjet always run superficial to and more obliquely than the major blood vessels along the lesser curvature. Myotomy of the whole lesser curve from the oesophagogastric junction to the incisura must provide separation of all nerve fibres which run with the serosa. Preservation of most of the major vessels does not preclude division of any nerve which might cross these along the line of myotomy, for the serosa over the vessel can be divided without damaging the latter. Following division of the serosa, oblique and superficial circular muscle wide separation of the divided serosa with its related nerves spontaneously occurs, wider separation being easily attained by blunt dissection with a pledget. Regeneration would require sprouting to occur across a 1–2 cm gap and for the minority of efferent nerves to grow along the appropriate axon sheaths. Such efficient nerve regeneration would seem unlikely and indeed acid secretory studies performed up to 1 year after myotomy do not show evidence of a major degree of regeneration. Amdrup and Griffith (1969) stated that in their experience the amount of mucosal reinnervation occurring as a result of the phenomenon of sprouting is insignificant.

The posterior myotomy is not difficult to perform. The posterior vagus runs down behind and separate from the oesophagus and upper gastric wall to the level of the left gastric artery where it becomes closely applied to the lesser curvature (Mitchell, 1940). The proximal end of the posterior myotomy is extended laterally below the oesophagogastric junction. As the nerves of Latarjet do not need to be identified and as adipose tissue does not extend across the gastric walls, obesity is not regarded as a contraindication to this procedure.

Insulin testing performed within 1 month of operation has shown that secretory inhibition at this stage is satisfactory and similar to that reported after highly selective vagotomy. There have been no early positive but four late positive responses, the acid output being comparable to that quoted by Amdrup and Jensen (1970). With increasing periods of time there has been a tendency for reversal of insulin status from negative to positive. The magnitude of this increase in acid output has not been great and appears to be quantitatively similar to that reported by Lyndon et al. (1975).

Although the clinical results following this operation are good and all our patients are well, the follow-up period is currently too short to permit full assessment. The final judgement of this procedure will rest on the incidence of recurrent ulceration. Longer term follow-up of highly selective vagotomy is now emerging, with a reported recurrence rate of 4·3 per cent from Dorricott et al. (1978) and Goligher et al. (1978) and of 5·4 per cent from Stoddard et al. (1978). There is no reason to believe from the secretory studies we have performed up to 1 year after myotomy that our incidence of recurrent ulceration should be any higher. Only time will tell, for it may still be regarded as early days for highly selective vagotomy as some recurrences after posterior gastroenterostomy alone occur after over 10 years.

Early experience with gastric emptying studies has shown no evidence of either early emptying or stasis and, of course, a drainage procedure is not required. The operation carries with it all the advantages associated with preservation of the innervated pylorus, the value of which has been shown with conventional highly selective vagotomy. Hart (1968) has reported that vagal antral nerves mediate inhibition of gastric acid secretion. Dragstedt has stated that: 'Tonus and hunger contractions of the stomach in patients with duodenal ulcer are usually excessive, a temporary atony of the fundic region was observed after vagotomy. It is very likely that this reduction in hypertonicity in part accounts for the immediate symptomatic relief so commonly produced' (Dragstedt and Owens, 1943). If gastric spasm is a factor in duodenal ulcer symptoms, then, in addition to dividing vagal branches, myotomy will aid in the prevention of such contractions.

Acknowledgements

The author is indebted to Professor A. P. M. Forrest for his help and advice; to Mr I. Ansell and Mrs Dorothy Gray for their technical assistance; to Mrs E. Watters who performed all tests of acid secretion; and to Mrs A. Dailly for her secretarial help. I am also most grateful for the clinical help given by members of the medical staff of the Department of Clinical Surgery, Edinburgh Royal Infirmary, in particular Mr David Lee.

Antibiotic-associated colitis—a review of 66 cases

G. A. G. MOGG, M. R. B. KEIGHLEY, D. W. BURDON,
J. ALEXANDER-WILLIAMS, DENISE YOUNGS, MARGARET JOHNSON,
SANDRA BENTLEY AND R. H. GEORGE*

SUMMARY

We have reviewed 66 cases of antibiotic-associated colitis since March 1975, which have been associated with a 27 per cent mortality. We believe antibiotics may predispose patients to this condition which is caused by a toxin produced by Clostridium difficile. Although the disease is rare, it is more common than previously reported. The presentation, methods of diagnosis and treatment are discussed.

PSEUDOMEMBRANOUS COLITIS was first described in the nineteenth century (Finney, 1893). In the past 30 years there has been renewed interest in the condition which has prompted many theories as to the aetiology of this disease. Initially, reports in the literature were based almost exclusively on post-mortem data. Sigmoidoscopy and rectal biopsy had rarely been performed. The bacteriological data that were analysed were usually from a swab taken at post-mortem and the culture media and bacteriological techniques were much less sophisticated than those of the present day. Penner and Druckerman (1948) reported on 9 fatal cases, 8 of whom had had an operation, and the conclusion was that 'shock' was the most important aetiological factor. However, it was argued that 'shock' was a result of the disease and not a prime cause (Dixon and Weisman, 1948).

A review of pseudomembranous colitis at the Mayo Clinic (Pettet et al., 1954) showed that there had been no increased incidence of the disease since the introduction of antibiotics. The disease was most commonly associated with operations for colonic carcinoma and it was suggested that the associated obstruction might be important.

A series of 8 cases of pseudomembranous colitis was reported in 1953 (Terplan et al., 1953) in which *Staphylococcus aureus* was identified in swabs taken from the mucosa in 5 of the patients. This observation was confirmed by many others (Speare, 1954; Hartmann and Angevine, 1956; Altemeier et al., 1963), and led to the belief that this organism was responsible for pseudomembranous colitis. However, many of the patients studied did not have a premortem stool culture and where this was performed the isolation rate of *S. aureus* was low. It was argued (Bloomfield and Waters, 1960) that the terms staphylococcal enterocolitis and pseudomembranous colitis were not synonymous but that the latter was a non-specific change to a variety of factors which might include staphylococcal enterocolitis. Furthermore, staphylococcal enterocolitis often involved the small bowel alone. Interestingly, the most successful treatment of this condition was the use of vancomycin (Wallace, 1965; Khan and Hall, 1966).

There has, however, been increasing evidence that antibiotics are a major predisposing factor for this disorder. Over 40 cases have been reported after exposure to lincomycin or clindamycin. The exact relationship of the disease to these two antibiotics is difficult to establish because they are often given in combination with other antibiotics. There have also been reports of pseudomembranous colitis being associated with other antibiotics: ampicillin (Keating et al., 1974; Simla et al., 1976); cephazolin (Fee et al., 1977); cotrimoxazole (Cameron and Thomas, 1977). In 1975 a viral aetiology was also proposed (Steer, 1975).

More recently, as a result of studies for a possible viral aetiology, a toxin was demonstrated from a patient with histologically proved pseudomembranous colitis (Larson et al., 1977). This toxin produced a characteristic cytopathic effect in cell culture which could be neutralized by *Clostridium sordelli* antitoxin. Subsequent studies in patients have demonstrated that this toxin was produced by *Clostridium difficile* (Bartlett et al., 1978; George, Symonds et al., 1978), which we now believe to be the cause of a type of pseudomembranous colitis.

We believe that the more appropriate term for the condition we have seen is antibiotic-associated colitis. The exact relationship between the presence of a faecal toxin and a pseudomembrane remains to be elucidated.

Patients and methods

We have reviewed our experience of antibiotic-associated colitis since March 1975 with respect to the method of presentation, the antibiotics prescribed, the method of diagnosis and the effect of the treatment prescribed.

In September 1977 we began routinely to screen all patients with diarrhoea for the presence of this faecal toxin using a HeLa cell culture to demonstrate this cytopathic effect (*Fig.* 1). At the same time routine bacteriology was performed for the identification of *Clostridium difficile*.

Results

We have reviewed 66 cases of antibiotic-associated colitis since March 1975. Prior to screening for the faecal toxin, we had seen 25 cases of this disease which had been diagnosed either histologically from a rectal biopsy or on post-mortem examination. Since September 1977 we have seen a further 41 cases up to February 1979, whose diagnosis was confirmed either histologically or on the presence of this faecal toxin.

Of these 66 patients, 28 were males with a mean age of 60·1 years (range 15–90); there were 38 females whose mean age was 59 years (range 29–88).

The associated disorders are reviewed in *Table I*. Fifty-six patients had one or more operations, of whom 37 (56 per cent) had disorders associated with the large bowel. Of these, 22 (33 per cent) had a carcinoma of the colon or rectum and there was evidence of obstruction in 10 patients in this group. The incidence of the disease is shown in *Fig.* 2 and there is evidence to suggest that epidemics of the disease may have occurred. This phenomenon has been reported by others (Kabins and Spira, 1975).

Others	2	1	38

Clinical presentation

Sixty-four patients had diarrhoea which was associated with colicky abdominal pain in 5 cases and abdominal distension with megacolon in a further 3 cases. No patient presented with either rectal bleeding or colonic perforation. The diarrhoea was usually watery but not offensive and often contained excess mucus but there was no pus or blood. The frequency of the diarrhoea was variable. The majority of patients had their bowels open between 3 and 8 times per day, but others had an even greater frequency.

Data on 60 patients showed that 40 (66 per cent) had a fever greater than 37·5 °C and of these 18 (26 per cent) had a fever of more than 38·5 °C.

Laboratory findings

Twenty-seven patients (41 per cent) had a white cell count greater than $15{\cdot}0 \times 10^9$/l (*Fig.* 3). Fifty patients (76 per cent) had a serum albumin below the lower limit of normal (*Fig.* 3) and of these, 16 (24 per cent) had a level below 25 g/l. The serum mucoproteins were estimated in only 17 patients. The mean level was 2·73 g/l with a range 0·95–5·10 g/l.

Bowel preparation and antibiotics

Bowel preparation was performed in 27 patients. Twelve patients had a whole bowel irrigation and the remaining 15 had a combination of other methods. The antibiotics prescribed were either given (*a*) preoperatively as part of the bowel preparation, (*b*) peroperatively, either with the premedication or in the anaesthetic room prior to operation, or (*c*) postoperatively, either as part of a prophylactic course or as therapy (*Table II*).

All patients had received antibiotics prior to developing the disease. A total of 205 courses of antibiotics were prescribed of which 150 (73 per cent) were given postoperatively. The groups of antibiotics prescribed reflect the nature of the surgery performed. Therefore, an aminoglycoside (most commonly gentamicin) and either lincomycin, clindamycin or more recently metronidazole were used extensively. Although some patients, especially those in the non-operated group, received a single antibiotic, many of those in the operated group received multiple courses.

Diagnosis

Prior to the introduction of screening for a faecal toxin, antibiotic-associated colitis was diagnosed histologically in 16 patients from a rectal biopsy and of these, 9 had a typical sigmoidoscopic appearance. However, the diagnosis was also made in a further 9 cases (36 per cent) only at post-mortem (*Fig.* 4).

Since September 1977, we have seen a further 41 cases. Thirteen patients (32 per cent) had sigmoidoscopic appearances of antibiotic-associated colitis which were confirmed histologically, as defined by the classification of Price and Davies (1977) and all had evidence of a faecal toxin. In 8 patients (19·5 per cent) no plaques were seen on sigmoidoscopy but there was histological and bacteriological evidence of antibiotic-associated colitis. In a further 11 patients (27 per cent) a faecal toxin only was found. However, the histology was reported as 'suspicious of antibiotic-associated colitis' or 'non-specific proctitis' in 8 patients in this group. Seven (17 per cent) patients had sigmoidoscopic and histological evidence of antibiotic-associated colitis but no faecal toxin was demonstrated. In only 2 patients was the diagnosis made at post-mortem. Barium enemas were performed on 10 patients, but the findings were not diagnostic and we no longer use this examination to establish the diagnosis. Other groups have reported similar findings (Shimkin and Link, 1973; Shapiro and Newman, 1973) though diagnostic features have been described (Sclafani et al., 1975). We have no experience with colonoscopy.

Mortality

There were 18 deaths in our series—a mortality of 27 per cent. Thirty patients were under the age of 60 years and there were 3 deaths (10 per cent) in this age group. There were 36 patients over the age of 60 and of these 15 died (41 per cent).

Treatment

Standard measures to control the diarrhoea proved ineffective. However, in a double blind trial of oral vancomycin (Keighley, Burdon et al., 1978) a rapid clinical response was reported. In the treated group there were 12 patients with *Clostridium difficile*, 9 of whom had a demonstrable faecal toxin. In the placebo group, there were 9 patients with *Clostridium difficile* of whom 7 had a faecal toxin. After 5 days of treatment with oral vancomycin in a dose of 125 mg four times a day, only one patient in the treated group still had the organism and a faecal toxin, whereas 8 patients in the placebo group still had *Clostridium difficile* and 6 still had the toxin. This reduction in the presence of toxin and the organism was accompanied by a marked improvement in the patients' symptoms.

In this series there are now 16 patients who have been treated with vancomycin. Eleven patients had a normal formed stool by the end of 5 days and the mean frequency of stools per day had fallen from 4·7 to 1·8. In the remaining 50 patients the mean duration was 15·3 days (range 4–50) with an average frequency of 6·2 stools per day (range 3–12).

Discussion

The incidence of the disease since the introduction of routine screening of all patients with diarrhoea is almost double that of the period prior to September 1977.

This may represent an actual increased incidence or alternatively an increased rate of diagnosis; we believe the latter has been the case. A number of patients develop diarrhoea especially after large bowel surgery and antibiotic therapy (Keighley, Alexander-Williams et al., 1978). This is often assumed to be 'resolution of the postoperative ileus'. Similarly, the presence of an elevated white blood count in conjunction with diarrhoea is sometimes indicative of sepsis following surgery. An elevated white blood count and diarrhoea may also occur in patients with antibiotic-associated colitis and under these circumstances the diagnosis of antibiotic-associated colitis will be missed if sigmoidoscopy and screening of faecal toxins are not performed. As a result of routinely investigating all patients who have had more than three loose stools per day or a colostomy output of greater than 1 l/day, we have diagnosed antibiotic-associated colitis in many patients in whom the disease would not previously have been suspected.

It has been suggested that we have experienced epidemics of this disease (*Fig.* 1) (June/July 1978). The reason for such outbreaks remains unresolved. An epidemiological study has failed to demonstrate a carrier state either in patients who have not previously had the disease or in the staff. However, the organism can be isolated from the faeces of children up to the age of 1 year (Hall and O'Toole, 1935). The possibility of cross-infection from infected patients or some other vector is being assessed.

The precise relationship between pseudomembranous colitis, antibiotics and the presence of toxigenic strains of *Clostridium difficile* remains to be defined. Until the pharmacology and pathogenesis of the toxin have been elucidated we believe the most appropriate term to describe the condition is antibiotic-associated colitis. This disease has been associated with many pre-existing conditions and in our series over half the cases were associated with disorders of the large bowel and a third occurred in patients with large bowel carcinoma. This, however, may only reflect the incidence of disease as seen in our gastrointestinal surgical unit.

Although antibiotic-associated colitis was considered to be specifically related to the use of lincomycin and clindamycin, we now know that other antibiotics have been implicated in patients developing the disease. Even short courses of antibiotics for prophylaxis have been shown to be responsible. Many of these antibiotics have been used in combinations which are known to exert an influence on the bacterial flora of the gastrointestinal tract. In a recent study (Keighley et al., 1979) it was shown that antibiotics which did not influence the microflora of the colon were not accompanied by antibiotic-associated colitis. These findings support the hypothesis that antibiotic-associated colitis may be due to an overgrowth of an organism normally present in small numbers within the colon.

Since September 1977, the diagnosis of antibiotic-associated colitis has only been confirmed sigmoidoscopically in 49 per cent of cases and histologically in 68 per cent. There are a number of factors which may explain the discrepancy between these results and the demonstration of a faecal toxin in 32 of our 41 patients (78 per cent). Careful sigmoidoscopy is required to identify the characteristic plaques as these may be obscured either by faecal fluid or by mucus adherent to the bowel wall. Gentle removal of this mucus is required otherwise the plaques may be dislodged, especially if the tip of the sigmoidoscope is used for this purpose. Secondly, if the biopsy does not incorporate a plaque, or more preferably a plaque/mucosa junction, the histological interpretation may be very difficult. Thirdly, repeat sigmoidoscopy is often required, possibly daily, before the classic morphological features are seen. There is a suggestion that the titre of faecal toxin is higher in patients with histologically proved disease than in those with 'non-specific' findings (Burdon, 1979). Finally, rectal sparing has been demonstrated at post-mortem examination. Although the presence of *Clostridium difficile* is not diagnostic of antibiotic-associated colitis we have isolated the organism in almost 90 per cent of our last 41 cases.

Treatment with vancomycin has proved an effective method of eradicating both the *Clostridium difficile* and its toxin; furthermore, vancomycin has been associated with a marked symptomatic improvement. General methods of treatment such as codeine phosphate and Lomotil (Searle) have proved ineffective. Indeed, the latter has possibly been associated with the development of toxic megacolon (Gibson et al., 1975). The demonstration that certain resins absorb the toxin (George, Symonds et al., 1978) offers possible treatment without the further use of antibiotics, which is appealing. In a recent study using cholestyramine (Kreutzer and Milligan, 1978) in a dose of 4 g/day, a good response was obtained in 12 patients with histologically proved disease.

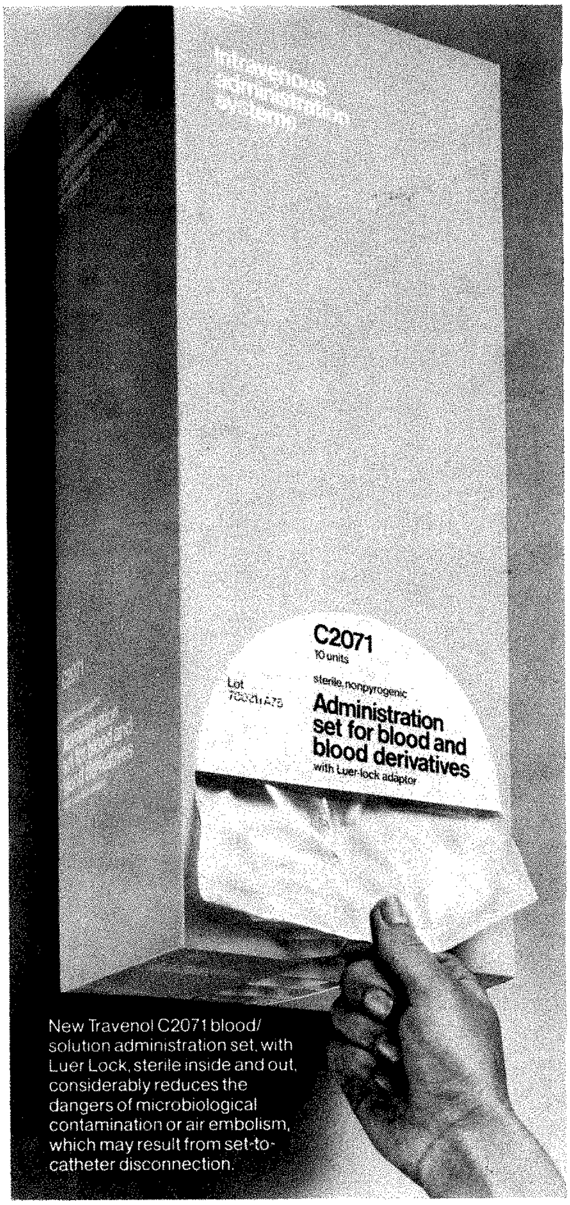
Travenol Sets the Standards



Intravenous administration systems
C2071
10 units
sterile, nonpyrogenic
Lot
Administration set for blood and blood derivatives
with Luer-lock adaptor

New Travenol C2071 blood/solution administration set, with Luer Lock, sterile inside and out, considerably reduces the dangers of microbiological contamination or air embolism, which may result from set-to-catheter disconnection.

Travenol intravenous administration sets exemplify three distinct standards of excellence.

A standard for design. Each set is designed to meet a known clinical need, and exhaustively tested to ensure that it does so.

A standard for manufacture. Rigorous quality control monitors every stage of production, from selection of raw materials to final sterilization, packaging and storage.

A standard for choice. The microbiological dangers of intravenous therapy can be reduced by choosing the right set for each procedure and so avoiding unnecessary connections.

For full details of the complete range of Travenol intravenous administration sets, please contact Marketing Services Department.

Travenol choice makes intravenous therapy safer

Prescribing Informati

Presentation:
Sterile, straw-coloured spherica
beads of dextranomer of 0.1-0.3
diameter, packed in plastic casto
single-use sachets.

Uses:
A dressing for moist, small area
burns, wounds and indolent ulce
whether clean or infected.

Dosage and Administration:
A 3mm layer of Debrisan should
sprinkled onto the wound and ke
in place by a pad of lint or a perfo
plastic sheet. Debrisan is hy
and the tissue exudate is drawn
into the layer. The Debrisan shou
renewed before saturation occu
Depending on the rate of exudati
this may be necessary from one
five times a day. Twice daily is usu
adequate. When Debrisan is chan
the old material is readily rinsed
with water or saline and new mat
may then be sprinkled onto the
wound.
Full instructions for use are encl
with each pack. Treated in this
manner the wound will remain so
and pliable during healing.

Contra-indications, Warnings,
1) Do not leave Debrisan for mo
than 24 hours on wounds with a
low exudation rate as it may dry
form a crust which may be difficu
wash off.
2) Occlusive dressings may lead
maceration of skin round the wo
under treatment.
3) When deep infected wounds a
treated, care must be taken to wa
Debrisan from the depths of the
wound.
4) No side effects have been repo

Warning:
Debrisan spillage can render sur
very slippery. Clear spillages pro

Precautions:
1) Not to be used on dry wounds
2) When exudate has been mark
removed by Debrisan alternative
treatment should be substituted
3) In order to avoid cross infecti
it is recommended that the conte
of a castor be confined to the tre
ment of a single patient for one d

Pharmaceutical Precautions:
Keep in a dry place in well closed
containers.

Packs and Price:
4g sachets in packs of 7 – Basic
NHS price £9.75.
Also available in 60g castors.

Legal Category: P.O.M.

Creating the healing environment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing, such as bacteria and wound debris.

Pain, oedema and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast.

Use Debrisan on all moist suppurating wounds such as pressure sores and leg ulcers.

Patients can enjoy the benefits of the healing environment of the future. Today.

Br. J. Surg. Vol. 66 (1979) 743–748

Anorectal Crohn's disease

N. S. WILLIAMS, J. MACFIE AND L. R. CELESTIN*

SUMMARY

Four hundred and twenty-three patients with Crohn's disease have been reviewed, 48 of whom had isolated anorectal involvement—an incidence of 11·4 per cent. These patients were compared with 48 randomly selected and sex-matched cases who presented with isolated ileocolic disease.

The age of the anorectal patients (53·6 ± 18 years) was greater than that of the controls (34·2 ± 12 years). The duration of follow-up was 6·0 ± 4 years and 12·6 ± 8 years respectively. Rectal bleeding, diarrhoea and perianal disease were more common in the anorectal group. Twenty-two patients (46 per cent) with anorectal disease and 40 (83 per cent) in the ileocolic group underwent definitive surgery. There were 4 (18 per cent) postoperative deaths in the anorectal group and none among the controls.

The incidence of recurrence was lower among the anorectal patients (21 per cent) compared with the ileocolic group (40 per cent). However, the estimated probability of recurrence, based on the duration of follow-up, the number of deaths during follow-up and the actual incidence of recurrence, is similar in both groups.

CROHN's disease may be confined to the rectum and anal canal with no evidence of disease elsewhere in the gastrointestinal tract. This variant of the disease has been termed anorectal Crohn's disease (*British Medical Journal*, 1976), and until recently there was little information available about it. Farmer et al. (1975) analysed the case records of 615 patients with Crohn's disease who presented to the Cleveland Clinic between 1966 and 1973. They found 21 patients (3·4 per cent) who presented initially with the disease localized to the anorectum but failed to give any detailed account of their clinical course. A more comprehensive review of this disease entity came from Ritchie and Lennard-Jones (1976) of St Mark's Hospital. These authors reviewed 80 patients with anorectal disease seen between 1940 and 1974. They concluded that anorectal Crohn's disease should be considered as a well-defined variant of the disease as it has a better prognosis and the mortality rate is low whatever treatment is employed. Furthermore, in contradistinction to Crohn's disease at other sites, recurrence or proximal spread after surgery is uncommon, so that surgery often results in cure.

As the management of Crohn's disease varies widely between different centres and results are assessed differently, we decided to review our own cases in the light of these recent articles.

Patients and methods

The case records of 423 patients with Crohn's disease treated at the General Infirmary, Leeds, and at Frenchay Hospital, Bristol, between 1939 and 1977 have been reviewed. Forty-eight patients presented with disease confined to the anorectal region—an incidence of 11·4 per cent.

The diagnosis was established by histological, sigmoidoscopic and radiological criteria. Although all patients did not have typical histological features of Crohn's disease, the radiological and sigmoidoscopic changes were considered to be compatible with Crohn's proctitis as defined by the following criteria.

Proctosigmoidoscopic features

Anal canal and perianal region: Demonstration of ulceration, fistulas, fissures, fleshy, oedematous skin tags or stricture of the anal canal.

Rectal mucosa: Evidence of inflammatory change, including mucosal oedema, friability and 'cobblestoning' of the mucosa. The presence of discrete ulcers, linear ulcers resembling fissures or areas of inflamed mucosa adjacent to normal mucosa (*Fig*. 1).

Radiological features

Evidence of rectal disease with or without distal sigmoid involvement, demonstrated by loss of mucosal pattern with 'cobblestone' mucosal changes, longitudinal or rake ulceration, fissuring and segmental involvement (Marshak and Lindner, 1967) (*Fig*. 2).

The diagnosis of anorectal Crohn's disease was only made if the disease was confined to the rectum and lower sigmoid colon with or without anal involvement. All cases included in the series were proved to have absence of disease elsewhere in the gastrointestinal tract either on radiological investigation, including small bowel meal, or on evidence from laparotomy. If the disease extended proximal to the left iliac crest on barium enema or was isolated to the perianal region or sigmoid colon alone, with no evidence of rectal involvement, the patient was excluded from the series.

As it has been previously suggested that anorectal Crohn's disease runs a more benign course and exhibits different clinical features from the more common ileocolic variety, we decided to compare our cases with 48 patients who presented initially with isolated ileocolic disease. These patients were randomly selected and matched for sex.

Results

We would point out that although statistically significant differences can be demonstrated between the two groups, these have not been quoted, as the two disease types cannot be considered to arise from the same population.

Age and sex: The mean age in the anorectal group was 54·7 years (range 17–77) and 35·4 years (range 15–71) in the ileocolic group (*Fig*. 3). There were 18 males and 36 females in both groups.

Histology: Typical histological features were noted in 28 patients (58 per cent) presenting with anorectal involvement and in 33 (69 per cent) with ileocolic disease. Non-specific inflammatory changes were demonstrated in the remaining patients in both groups.

Follow-up: The mean duration of follow-up was 6·1 years and 12·3 years respectively. In 7 patients of the anorectal group and in 5 of the ileocolic group follow-up was incomplete.

Clinical features: These are summarized in *Table I*. As would be expected, diarrhoea and rectal bleeding were more common in patients with involvement of the distal colon. Of the 27 patients with perianal disease in the anorectal group, 12 had presented

Salazopyrin	20	2
Azathioprine	5	0
Other	5	4

* Percentage of 48 cases.

several months or years before the diagnosis of Crohn's disease was established. The major complaint in 6 patients with ano-rectal disease was of intractable constipation, subsequently shown to be due to a rectal stricture. Associated symptoms included 7 patients with polyarthritis and 1 with erythema nodosum in the anorectal group compared with 3 cases of polyarthritis and 1 of irridocyclitis in the ileocolic group.

It should be noted that 7 of the 48 patients with anorectal disease had concomitant involvement of the distal sigmoid.

Treatment

Conservative (*Table II*): Drug therapy was the initial treatment in 37 of the anorectal group and 13 of the ileocolic group. The numbers of patients listed in *Table II* refer to drug therapy prescribed on presentation only. Steroid therapy involved systemic steroids in both groups. Topical steroids were commonly prescribed in the anorectal group but patients are not listed in *Table II* unless they also received systemic therapy. Salazopyrin was prescribed in 20 patients with anorectal disease, 15 of whom had concomitant steroid therapy.

Surgery: Twenty-two patients (46 per cent) with anorectal disease and 40 (83 per cent) with ileocolic disease underwent definitive surgery.

Indications (*Table III*): The most common indications for surgery in the anorectal group were rectal bleeding (64 per cent), persistent diarrhoea with mucopus (36 per cent) and intractable constipation as a result of rectal stricturing (27 per cent). Abdominal pain (48 per cent), intestinal obstruction (33 per cent) and diarrhoea (30 per cent) were the most frequent indications for surgery in patients with ileocolic disease.

Results of surgery: The surgical procedures performed and the results of surgery are shown in *Table IV*.

Operative mortality: There were 3 postoperative deaths in the anorectal group and none in the ileocolic. There was one further death in the anorectal group in a patient undergoing further surgery for recurrence.

Subsequent surgery: The numbers of patients who required further definitive surgery for Crohn's disease are shown in *Table IV*. It should be emphasized that not all patients were reoperated upon for recurrent disease.

Anorectal group: Of 7 patients who initially underwent a bypass procedure (defunctioning colostomy or ileostomy) 1 died and 5 required further surgery, of whom 3 had proved recurrence. Fifteen patients had a primary resection and the operative procedures are shown. There were 2 postoperative deaths and only 2 patients required further surgery, both of whom had previously had a rectal excision.

Ileocolic group: Of 23 patients who initially had a bypass, exploration or appendicectomy alone, 12 required further surgery. Only 5 of these cases had proved recurrence, the remainder undergoing surgery for excision of their original lesion. Seventeen patients had a primary excision, 9 of whom required further surgery, all for recurrence.

Recurrence

Patients with continuing symptoms or patients in whom a bypass procedure was performed initially have not been included in the analysis of recurrence unless there was definite evidence that the disease process involved a different site from that on presentation.

Ten patients (21 per cent) with anorectal disease and 19 (40 per cent) with ileocolic disease had proved recurrence. The mean time interval between initial diagnosis of the Crohn's disease and the confirmation of recurrence was 5·7 years and 5·8 years respectively. *Fig.* 4 shows the estimated probability of recurrence based on life table calculations (Berkman and Gage, 1950).

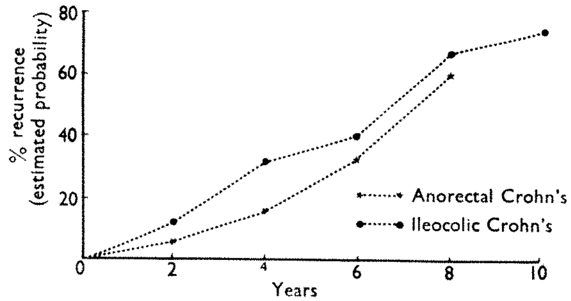

Fig. 4. Estimated probability of recurrence plotted against time. (Based on life table calculations adopted from Berkman and Gage, 1950.)

The probability of recurrence is similar in both groups despite the finding that there is a difference in actual incidences. This apparent discrepancy is explained by the large difference in the numbers of deaths that occurred during follow-up in the respective groups (anorectal 11; ileocolic 3).

Site: *Table V* illustrates the frequency of recurrence at various sites in the gastrointestinal tract as well as the total number of episodes of recurrence in the two groups. In the majority of patients with anorectal disease the recurrence was within the large bowel. Conversely, in most patients presenting with ileocolic disease who showed recurrence, this was in the ileum.

Treatment of recurrence: Table VI summarizes the treatment of recurrent disease. All the patients with anorectal disease who underwent surgery for recurrence required further colonic resection.

Discussion

It is commonly stated that in about 50 per cent of patients with Crohn's disease of the large bowel the rectum is not involved (Goligher, 1975). Indeed, many clinicians regard rectal 'sparing' as an important clinical feature in distinguishing between Crohn's disease and ulcerative colitis. That the rectum may be involved with no evidence of disease elsewhere has only recently been appreciated (*British Medical Journal*, 1976). Since the information regarding this variant of the disease is sparse, it is difficult to know its true incidence, but it would seem to be low—about 4 per cent according to Farmer et al. (1975). An incidence of over 11 per cent in our series is therefore surprising. Since Leeds General Infirmary has a particular interest in large bowel surgery it was thought that this might predjudice the results. However, this has not been found to be the case, since the incidence of the disease in the cases from Bristol, where this bias does not apply, is the same.

Diagnosis of this distal form of Crohn's disease and its differentiation from non-specific proctitis or distal ulcerative colitis may be difficult. The finding of typical histology (Hadfield, 1939; Lockhart-Mummery and Morson, 1960, 1964) on biopsy is conclusive evidence but, often, one has to rely on clinical, radiological and sigmoidoscopic evidence. This difficulty is represented in our series, as only 58 per cent of the anorectal patients had characteristic histological findings. It must be emphasized, however, that the remaining patients were only included in the series if they fulfilled the strict diagnostic criteria previously described.

There is little doubt that patients with anorectal disease present in a different way from patients with ileocolic disease. The patients with anorectal disease are older, the majority (62 per cent) being over 50 years of age (*Fig.* 1). The most common presenting symptoms were, as expected, rectal bleeding and diarrhoea (*Table I*). Not surprisingly, abdominal pain and intestinal obstruction with or without an abdominal mass were common clinical features in the patients with ileocolic disease. Perianal disease occurred more frequently in the anorectal group and this finding is compatible with results from other authors who have shown that the more distal the disease, the greater the incidence of perianal lesions (Morson and Lockhart-Mummery, 1959; Fielding, 1972). An incidence of 57 per cent, however, does not confirm the statement of Lockhart-Mummery (1972) that when the rectum itself is involved the incidence of these lesions is nearly 100 per cent. It is well known that perianal involvement may precede the onset of intestinal disease, and indeed for some time may be the only manifestation of the disease. Our findings do not differ in this respect, as 12 of our patients presented initially with perianal disease several months to years before the rectal involvement declared itself.

Crohn's disease situated anywhere in the gastrointestinal tract may produce stricture formation. The rectum does not appear to be an exception, as 6 patients presented with intractable constipation subsequently confirmed to be due to a Crohn's stricture. Two further patients in the anorectal group who presented with rectal bleeding and the passage of mucopus were diagnosed as cases of rectal carcinoma. In both cases perianal disease was absent, sigmoidoscopy and barium enema examination were suspicious of carcinoma but preoperative biopsy was inconclusive. The correct diagnosis was finally confirmed after section of the surgical specimen. This emphasizes the importance of taking multiple biopsies in all patients with a rectal stricture.

The same spectrum of associated conditions occurs in anorectal disease as in the ileocolic variety, although arthritis is more common. This may be related to the older age of the anorectal patients, but it is interesting to note that Greenstein et al. (1976) found arthritis to be the most common complication of Crohn's colitis.

Drug therapy for Crohn's disease is difficult to rationalize as there have been few controlled prospective therapeutic trials. We believe, however, that the simplest drugs available to control symptoms should be employed. Therefore the policy in both units for treating this distal form of the disease is a conservative one, using local steroid preparations with or without Salazopyrin in the first instance. Systemic steroids are used if these measures fail or if the disease causes general ill health. Azathioprine is reserved for use only in those cases failing to respond to the previous measures.

It will be appreciated that it is difficult to draw any firm conclusions about differences in drug therapy in any retrospective study as one is never completely sure about the completeness of the data. However, it should be noted that a total of 34 patients (71 per cent) with anorectal disease required either oral steroids or azathioprine in comparison to 8 patients (17 per cent) in the ileocolic group (*Table II*). This suggests that symptoms were more severe in our patients than in

Quite an opera

When it comes down to it, any operation can only be rated successful if it produces the required result. And tying up the loose ends is important at the end. Thats why Key Med's operation maintains a veritable army of specialists—a skilled task force of experts, disciplined not only to meet the needs of today, but to anticipate and deal with the challenges of the 80's. cefuroxime sodium

Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics.

Zinacef resists destruction by beta-lactamases
A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.

the 80 patients reported from St Mark's Hospital (Ritchie and Lennard-Jones, 1976), where only 22 patients (27 per cent) required these drugs.

There is little information in the literature concerning the surgical management of this variety of the disease. Ritchie and Lockhart-Mummery (1973) reported on 26 patients treated surgically. A defunctioning colostomy was performed in 7 of these patients but proved ineffective in controlling symptoms. The remaining patients were treated successfully by abdominoperineal resection of the rectum with no operative mortality. As can be seen from *Table IV*, 22 patients (46 per cent) in our series required surgery as compared with 40 (83 per cent) in the ileocolic group. The indications for surgery in the anorectal patients are summarized in *Table III*, the most common being severe rectal bleeding. Four patients (18 per cent) in the anorectal group died in the postoperative period, 3 following the initial surgical procedure and 1 following a second operation for recurrence. There were no operative deaths in the ileocolic group despite the greater number operated on. Perhaps this difference reflects the greater age of the patients with anorectal disease.

It is generally accepted that excision is the best form of surgical treatment for Crohn's disease of the colon. In 1968 Oberhelman et al. recommended, as an alternative, temporary exclusion of the entire large bowel by means of an ileostomy. These authors claimed that, unlike ulcerative colitis, the disease became quiescent when the diseased segment was excluded. Several other workers (Jones et al., 1966; Burman et al., 1971; McIlrath, 1971), however, have found the long term results of bypass surgery to be unsatisfactory. As regards anorectal disease, our findings support an aggressive approach. Of the 7 patients submitted to a defunctioning procedure as the primary procedure, 5 required rectal excision at a later date. This contrasts sharply with the 15 patients who underwent excision in the first instance, only 2 of whom required a second operation.

The question inevitably arises as to how extensive the excision should be in patients with this variety of the disease. In dealing with Crohn's disease of the small bowel most experienced surgeons remove 20–25 cm of healthy bowel both proximal and distal to the diseased segment. As far as anorectal disease is concerned, the problem is whether to perform an abdominoperineal resection of the rectum or a proctocolectomy. Unfortunately, the number of patients in our series is too small to make any recommendations. It is interesting, however, that of the 7 patients who underwent abdominoperineal resection initially, 3 developed recurrence in the remaining colon, whereas of the 4 patients surviving proctocolectomy, none developed recurrence.

When discussing recurrence it is essential to define what one means. Contrary to some authors (Lennard-Jones and Stalder, 1966), we have not accepted a relapse of symptoms as indicating recurrence, unless it was accompanied by firm supporting evidence of further disease, usually from laparotomy but sometimes from radiological study. Also, following a bypass or defunctioning procedure, we do not regard disease remaining in the defunctioned segment as a recurrence, preferring to use this term only when disease has been found elsewhere. With regard to these stipulations, 10 patients in the anorectal group showed recurrence, compared with 19 in the control group. We believe that this may not reflect a true difference between the two groups mainly because the mean follow-up period is much shorter in the anorectal group. Indeed, if the estimated probability of recurrence is calculated for the two groups, it appears that after 8 years the number of patients suffering recurrence may become equal (*Fig.* 3).

Our results confirm that anorectal Crohn's disease does present in a manner different from ileocolic disease. It occurs in an older age group and presents with different clinical features. Whether or not it can be considered as a more benign variant of the disease, however, is debatable. Although 54 per cent of our patients avoided surgery, the majority required potentially toxic drugs to keep the disease in remission. When surgery was required this was often of a major nature performed in elderly patients and this is reflected in the higher operative mortality rate. Furthermore, these patients have an incidence of recurrence of 21 per cent which may increase with an extension of follow-up to approach that of ileocolic disease.

In conclusion, we would suggest that Crohn's disease is a single disease entity, albeit with certain definable patterns of presentation depending on the site of involvement, and anorectal Crohn's is one example of this. Given sufficient time, however, the disease will behave in a similar manner irrespective of where it initially develops.

Is the investigation of patients with breast cancer for occult metastatic disease worth while?

A. P. M. FORREST, ELIZABETH L. M. CANT, M. MAUREEN ROBERTS, HELEN J. STEWART, M. D. SUMERLING, A. A. DONALDSON, A. F. SMITH AND A. A. SHIVAS*

THE main problem affecting the treatment of breast cancer is that systemic spread to bones, liver, lungs, brain and other sites has taken place in the majority of patients who present with early disease. As with other malignancies, accurate determination of the extent of breast cancer will become an essential prerequisite to rational management, which must include consideration of systemic as well as local treatment.

The methods which are routinely applied to determine this are of low sensitivity. Routine radiographs of chest and skeleton and routine liver function tests detect unsuspected metastases only in a few patients with early disease. Emphasis has therefore been placed on the importance of determining the histological state of the axillary lymph nodes as an indicator of likely metastatic spread elsewhere. Those with proved node involvement are well known to have disease of bad prognosis, and therefore are eligible to be included in trials of systemic therapy (Fisher et al., 1969).

The development of more sensitive methods to detect otherwise occult metastatic disease in bones, liver and brain by isotope scintigraphy, ultrasonography and CT scans, by more sensitive liver function tests and by estimation of breakdown excretion products, e.g. urinary hydroxyproline, has stimulated interest in their use as staging methods in breast cancer.

In 1974, rather than use these techniques in an *ad hoc* way, we decided to carry out a prospective study in which all patients with early breast cancer attending our clinic had a strict programme of assessment before investigation. The objectives were to determine the proportion of patients with early disease in whom occult metastases would be suspected by these methods, to relate the findings to the histology of the lower axillary (pectoral) lymph nodes which were sampled at the time of primary treatment and to correlate both of these to the subsequent progress of the disease. The determination of 'operability' therefore did not include knowledge of the results of these tests but was by normal clinical staging.

Table I: TREATMENT PROTOCOL

Day 1	Start gelatin-free diet Radiological survey of skeleton Skeletal scintiscan Blood for alkaline phosphatase and γ-glutamyl transpeptidase
Day 2	Continue diet
Day 3	Continue diet First collection 24-h urine
Day 4	Continue diet Second collection 24-h urine Liver scintiscan Blood for alkaline phosphatase and γ-glutamyl transpeptidase

Patients and methods

Over 200 women with UICC stages I, II and operable III (T3 on size) breast cancer have been studied, all with negative chest and skeletal radiographs. This report is of the first 172 patients, all of whom have been regularly followed up for 1–4 years.

The investigations were carried out over a 4-day period in an assessment unit in a small 5-day hospital. These were designed to detect occult metastatic disease in bone and in liver and included skeletal scintigraphy, urinary hydroxyproline excretion on a gelatin-free diet, hepatic scintigraphy and estimations of plasma, γ-glutamyl transpeptidase and alkaline phosphatase. Except where indicated, the protocol remained constant for the whole study, the investigations being carried out on identical days (*Table I*).

Scintigraphy: All scans were performed using a Nuclear Enterprise mark IV gamma camera. The isotope used initially for skeletal imaging was ^{99}Tc^{m}-hydroxyethylidine disodium phosphate but latterly this has been ^{99}Tc^{m}-disodium etidronate stannous chloride (Osteoscan). Between 10 and 15 mCi were injected intravenously and 10–15 images taken at 3 h. These included anterior and posterior pelvis, right and left anteroposterior sternum, right lateral skull, lumbar, thoracic and cervical spine, right and left shoulder and ribs.

For liver imaging 2 mCi ^{99}Tc^{m}-sulphur colloid were injected intravenously and three images (anterior, lateral and posterior) taken after 15 min. All scans were first reported by members of the Department of Radiology but were subsequently reviewed along with skeletal X-rays by M. D. S. with E. L. M. C. or M. M. R. A positive bone scan was one in which there were areas of increased uptake which could not be explained by radiological evidence of benign disease. A positive liver scan was one showing areas of decreased uptake.

Urinary hydroxyproline: Patients were placed on a gelatin-free diet for 4 days and urine collected during days 3 and 4 into clean Winchester bottles containing 8 g boric acid as preservative. Estimates of hydroxyproline were performed by the methods of Ellis and Goldberg (1970). Creatinine was estimated by autoanalyser. The results were expressed as the total output of hydroxyproline in mg/24 h and as the hydroxyproline : creatinine ratio (mg/g creatinine). As a result of studies in normal women, abnormal values were set at $\geqslant 33{\cdot}0$ mg/24 h for total output and $\geqslant 31{\cdot}0$ mg for the hydroxyproline : creatinine ratio. For the purpose of this study, an abnormality of either one was regarded as an abnormal hydroxyproline excretion.

Once studies in 93 patients had established that there was no difference in the values of the collections taken on days 3 and 4 of the gelatin-free dietary period, only day 3 was used for collection and estimation.

γ-Glutamyl transpeptidase: This was estimated by a kinetic reaction at 37 °C using γ-glutamyl nitrolalide as substrate. A value of 35·0 units or more was taken as abnormal.

Alkaline phosphatase: This was estimated by autoanalyser using *p*-nitrophenyl acid phosphate as substrate. When abnormal values were depicted (>100 units per litre) polyacrylamide gel electrophoresis was used to determine whether these were due to bone or liver isoenzymes (Warwick et al.,

Table II: INCIDENCE OF POSITIVE TESTS IN 172 PATIENTS WITH BREAST CANCER OF STAGES I, II AND OPERABLE III

	No. of patients
Suspected bone metastases	40
Scintiscan positive	12
Increased output urinary hydroxyproline or hydroxyproline : creatinine ratio	26
Elevated alkaline phosphatase	9
Suspected liver metastases	21
Scintiscan positive	11
Elevated γ-glutamyl transpeptidase	13
Elevated alkaline phosphatase	2

Table III: THE INCIDENCE OF SUSPECTED OCCULT METASTATIC DISEASE IN RELATION TO NODE STATUS

	No. of patients	No. with suspected metastases
Nodes involved by tumour	75	28 (37%)
Nodes not involved by tumour	73	20 (27%)
Nodes not identified by surgeon and/or pathologist	24	5 (21%)
Total	172	53 (31%)

χ^2 of nodes involved versus others, 2·774 $P<0{\cdot}10$.

Table IV: POTENTIAL VALUE OF TESTS FOR OCCULT DISEASE OVER NODE STATUS IN WHOLE SERIES OF 172 PATIENTS IN DEFINING DISEASE OF BAD PROGNOSIS

Definition of 'bad prognosis'	No. of patients	% of 172 patients
Nodes involved histologically (with or without positive tests)	75	44
Negative (or non-identified nodes) but positive tests	25	14
Total	100	58

1972). Initially two blood samples were taken from each patient for γ-glutamyl transpeptidase and alkaline phosphatase estimations. As there were no differences, a single sample was subsequently taken.

CT brain scans: A sample of 40 consecutive patients within this series had CT brain scans performed, seeking evidence of occult metastatic cerebral disease, either by focal areas of abnormal density or by the demonstration of discrete opacities.

Sodium diatrizoate (500 ml) (Urografin, Schering) was injected intravenously for contrast enhancement. Each patient had a total of 8 scans performed, 4 with contrast enhancement and 4 without, using initially an EMI mark I scanner and latterly a CT 1010 scanner.

Treatment

It was intended that all patients be treated in an identical way. In the event, 168 patients were treated by total mastectomy and pectoral (lower axillary) node sampling. On account of age, 3 had a local excision with axillary node biopsy and 1 was treated by radiotherapy alone. Nodes were identified for histological examination in 148 patients, of whom 75 had positive and 73 negative nodes. In the remaining 24 patients nodes were not identified by either the surgeon or the pathologist. All patients have been followed up at intervals of 4 months. A review of the records of all 172 patients was undertaken in March 1979 and the current state of all patients confirmed. No patient has been lost to follow-up.

Results

CT brain scans: None of the 40 patients investigated by CT brain scans had any abnormality demonstrated. For this reason this investigation was discontinued.

Table V: INCIDENCE OF RECURRENT DISEASE IN THOSE WITH OR WITHOUT POSITIVE TESTS FOR OCCULT METASTATIC DISEASE AT THE TIME OF MASTECTOMY

Status at mastectomy	No. of patients	No. with recurrence
Suspected metastatic disease bone or liver or both	53	14 (26%)
All tests negative	119	35 (29%)

χ^2 of difference 0 134.

Table VI: RELATIONSHIP BETWEEN RECURRENCE AT 1–4 YEARS, NODE STATUS AND TESTS FOR OCCULT METASTATIC DISEASE AT TIME OF MASTECTOMY

Node histology	Tests for occult disease	No. of patients	No. with recurrence
Positive	Positive	28	8 (35%)
Positive	Negative	47	23 (49%)
Negative or not identified	Positive	25	6 (24%)
Negative or not identified	Negative	72	12 (17%)

Suspected metastases in bone and liver: Forty of the 172 patients (23 per cent) had one or other test for bone involvement positive and therefore were regarded as having a suspicion of metastatic bone disease, 21 patients (12 per cent) had a suspicion of liver metastases on similar grounds and 53 patients (31 per cent) one or other or both. The incidence of abnormal tests is given in *Table II*. Only 1 of the 40 patients with suspected bone metastases had all three and 5 had two tests positive; only 1 of the 21 patients with suspected liver metastases had all three and 3 patients had two tests positive. The other 34 patients with suspected bone metastases and 17 with suspected liver metastases had only one abnormal test.

Relationship to node status: The relationship between positive tests and pectoral node histology is shown in *Table III*. Although there is a trend towards more positive tests in those with involved nodes than those with either negative or non-identified nodes, this does not reach statistical significance. These tests for occult metastatic disease, compared with information on node status only, defined an additional 14 per cent of patients who could be presumed to have disease of bad prognosis (*Table IV*).

Recurrence: Forty-nine of the 172 patients (28 per cent) have developed recurrent disease. The incidence is no greater in those suspected to have occult metastatic disease at the time of mastectomy than in those in whom tests for metastatic disease were negative (*Table V*). There is also a disappointing relationship between positive tests and the site of recurrence. Only 8 of the 40 patients with suspected bone involvement have developed overt bone metastases; and only 4 of 21 with suspected liver involvement have developed overt liver metastases. This incidence is less than that observed in the 119 patients in whom all tests proved to be negative, 35 of whom have developed overt bone or liver disease.

In *Table VI* the relationship between the incidence of positive tests for occult metastatic disease, node status (grouping negative and non-identified nodes together) and recurrence is given. Those with positive nodes have high recurrence rates irrespective of the results of the superstaging tests which have contributed little to the recognition of bad prognosis. In those patients with negative (or non-identified) nodes these tests for occult metastatic disease did appear to contribute to the definition of a good prognosis group and patients with negative (or non-identified) nodes and negative superstaging tests had a particularly low recurrence rate. However, this is not of statistical significance (Cant et al., 1977).

Conclusions

Although a longer follow-up is required to be certain of the validity of the conclusions, these data do suggest that a strict protocol of assessment of patients with early breast cancer for occult metastatic disease does not contribute to the definition of those with disease of bad prognosis. Although such tests were positive in 30 per cent of patients, they were of little additional value over the histological state of the axillary nodes, and at best would only identify a further 14 per cent of patients with potentially bad disease. Even this is doubtful, as the relationship between positive tests and subsequent recurrence is poor.

Meantime, the histological state of the axillary lymph nodes is still the best indicator of likely metastatic spread, and removal of nodes for histological examination is an essential part of the initial management of the disease, irrespective of the type of primary treatment.

SUMMARY

Three hundred and fifty-four women with primary operable breast cancer had a bone scan performed within 6 weeks of a simple mastectomy. Eight (2·3 per cent) were positive, but 7 of these patients had radiological evidence of bony metastases. Follow-up bone scans 1 year postoperatively on 278 patients showed only 12 (4·3 per cent) positive, and of these, 9 had other radiological evidence of metastatic disease. At 2 years postoperatively there were 13 (9·2 per cent) positive bone scans amongst 141 patients. Only 2 of these 13 had no other evidence of metastases. Although a bone scan is a useful investigation in patients with bone pain, there is no place for routine bone scanning in either the staging or follow-up of women with operable breast cancer.

THE incidence of positive bone scans performed at the time of mastectomy in patients with clinically operable breast cancer is reported in different series as varying from 1·9 to 20·2 per cent (British Breast Group, 1978). In spite of this unexplained disparity, a bone scan is still the most sensitive method of showing symptomatic bony metastases (Sklaroff and Charkes, 1968; Citrin et al., 1975; Galasko, 1975). In 1975 Galasko reported that 24 per cent of 50 patients with apparently 'early' breast cancer had a positive bone scan at the time of mastectomy. He went on to show that 83 per cent of those patients with a positive scan were dead within 5 years of mastectomy, an observation confirmed by Campbell et al. (1976) and McKillop et al. (1978). McKillop and co-workers concluded that serial bone scanning is of considerable value in the follow-up of these women and that a positive bone scan is a bad prognostic sign.

It has previously been reported from Nottingham (Davies et al., 1977) that although a positive scan is a bad prognostic finding, it identifies only a few of those patients who subsequently develop a major recurrence and that lymph node biopsy at the time of mastectomy gives a great deal more information in this respect.

In this paper further experience with bone scans performed in Nottingham is reported together with the results of sequential bone scans in the first 2 years following mastectomy.

Patients and methods

Between 1973 and 1978, 354 patients aged between 26 and 75 years with primary operable breast cancer were admitted under the care of one surgeon (R. W. B.). Patients were considered to have primary operable breast cancer if they had a breast tumour that was less than 5 cm in diameter on clinical examination, with no clinical evidence of distant metastases. All the patients underwent a simple mastectomy with biopsy of the axillary, apical and internal mammary nodes. A base line bone scan, chest X-ray and skeletal survey were performed within 6 weeks of operation. Postoperatively the patients were followed up in a special post-mastectomy clinic at 3-monthy intervals for 18 months and thereafter at 6-monthly intervals. At each attendance the patients were examined clinically and blood was taken for haemoglobin, white cell count, ESR, liver function tests and calcium levels. An annual bone scan and chest X-ray were performed on each patient. Any areas of increased or abnormal uptake demonstrated by the scan were then examined by conventional radiographs. Patients were scanned with either an Ohio Nuclear Rectilinear scanner or a Searle LFOV gamma camera; ^{99}Tc^{m} polyphosphates and diphosphonates have been used throughout the study. The first 87 patients were scanned by the X-ray Department at the General Hospital, Nottingham. The three subsequent cohorts consisted of 94, 78 and 95 patients each and were all scanned by the X-ray Department at the City Hospital, Nottingham. Only the fourth cohort, 95 patients, has been scanned with the gamma camera. Three possible interpretations of the scans were allowed: negative for bony metastases, equivocal and positive for bony metastases. In this paper an equivocal result has been classed as negative (Davies et al., 1977).

Results

At the time of mastectomy

Three hundred and fifty-four patients had a bone scan performed in the immediate postoperative period. Of these, only 8 (2·3 per cent) were positive (*Table I*). Seven out of these 8 patients had metastases visible on conventional X-rays done at the same time as the scan. Only 1 patient out of 354 (0·3 per cent) had a positive bone scan without radiological evidence of metastases. This patient had no other evidence of distant metastases at the time of her mastectomy (she did have lymph node invasion at mastectomy). Three months later, she developed an oculomotor palsy and this was shown by a brain scan to be due to a cerebral metastasis.

One patient had radiological evidence of sclerotic bony metastases at the time of mastectomy which the bone scan failed to demonstrate—in other words, a false negative result. A year later these metastases were picked up by the bone scan. The patient's X-rays at that time showed considerable progression of the lesions.

Four patients (1·1 per cent) had a false positive bone scan result, i.e. their scans were classified as being positive for bony metastases. However, after a minimum follow-up of 30 months, sequential scans and X-rays have shown these 'hot spots' either to disappear completely or else to remain unchanged; clinically all 4 patients remain well with no clinical evidence of recurrence. It seems reasonable to assume that these are genuine false positive results.

At 1 year postoperatively

To date 278 patients have had a bone scan performed 1 year postoperatively, with a positive result in 12 (4·3 per cent) (*Table II*). Of those 12 patients, 7 had bony metastases visible on plain X-rays. Two patients had a positive bone scan, and although bony metastases could not be detected by conventional radiographs, their chest X-rays showed lung metastases. Only 3 out of 278 patients (1·1 per cent) had a positive bone scan with no other radiological evidence of metastases. Of these 3 patients, 1 developed clinically apparent liver metastases 6 months later, 1 started to develop bone pain a year after her scan became positive and only at this time did her X-rays confirm the presence of osteolytic metastases and the third remains well 3 months after her positive bone scan result with no evidence of metastases on X-ray.

At 2 years postoperatively

Not enough patients in the fourth cohort have yet been scanned at 2 years to be included in an analysis of our results, therefore the results for scans done at 2 years are taken from the first three cohorts only (*Table III*). To date, 141 patients have had a bone scan performed at 2 years. Thirteen scans (9·2 per cent) were positive. Six of these 13 patients had bony metastases visible on conventional X-rays done at the same time. One of these 13 had obvious lung metastases on her chest X-ray. Three patients in this group had developed clinical evidence of soft tissue metastases before the demonstration of occult bony metastases on the routine scan. Therefore only 2 patients (1·4 per cent) had a positive bone scan with no other evidence of metastases. In 1 patient the interval between the positive bone scan and clinical evidence of metastases was 19 months, the other remains well with no X-ray or clinical evidence of recurrence 1 year after her positive bone scan.

Discussion

Scanning at the time of mastectomy

In Nottingham the incidence of positive bone scans at the time of mastectomy is 2·3 per cent—the previous report on only 192 cases put the figure at 4·7 per cent (Davies et al., 1977). These results are in the same range as the results reported by Green et al. (1973), Lentle et al. (1975), El-Domieri and Shroff (1976), Baker et al. (1977) and Gerber et al. (1977). This low percentage of positive results is in sharp contrast to the very much higher figures obtained by Campbell et al. (1976), Roberts et al. (1976) and McKillop et al. (1978).

The statement on bone scanning published by the British Breast Group (1978) revealed a very wide variation in the reported incidence of positive bone scans. Two London centres, Guy's and Charing Cross, had between them the lowest and highest rates respectively: 1·9 per cent for Guy's and 20·2 per cent for Charing Cross. The very wide difference in the percentage of positive bone scans found at the time of mastectomy by different authors is an important and unsolved problem.

Although 2·3 per cent of our initial scans were positive, only 1 (0·3 per cent) was positive without other X-ray evidence of metastases at the same site. This represents an enormous effort for a very tiny yield of information. Another point to emerge from scanning at the time of mastectomy is that there are nearly as many false positive as true positive scans. Approximately 40 per cent of patients with operable breast cancer will be dead or will have had a major recurrence within 5 years of operation (Brinkley and Haybittle, 1975). It is difficult to see how, with a positive incidence of 2·3 per cent, bone scanning can seriously be considered as contributing to the initial overall prognosis of patients with breast cancer. All a positive bone scan suggests is that that particular patient will do very badly in terms of morbidity and mortality.

Table I: EARLY POSTOPERATIVE BONE SCAN RESULTS ($n = 354$)

	Cohort 1st	2nd	3rd	4th	Total
Positive	2	2	1	3	8 (2·3%)
Negative	83	90	76	92	341 (96·3%)
False positive	2	2	0	0	5 (1·1%)
False negative	0	0	1	0	1 (0·3%)

Table II: BONE SCAN RESULTS IN THE FIRST POSTOPERATIVE YEAR ($n = 278$)

	Cohort 1st	2nd	3rd	4th	Total
Positive	2	4	4	2	12 (4·3%)
Negative	72	81	66	43	262 (94·2%)
False positive	1	0	0	0	1 (0·4%)
False negative	1	1	0	1	3 (1·1%)

Table III: BONE SCAN RESULTS 2 YEARS POSTOPERATIVELY ($n = 141$)

	Cohort 1st	2nd	3rd	Total
Positive	6	6	1	13 (9·2%)
Negative	56	58	12	126 (89·4%)
False positive	1	0	0	1 (0·7%)
False negative	1	0	0	1 (0·7%)

To date not enough patients in the fourth cohort have been scanned at 2 years to be included (*see* text).

Table IV: BONE SCAN RESULTS

	Postop. ($n = 354$) (%)	1st year ($n = 278$) (%)	2nd year ($n = 141$) (%)
Positive	2·3	4·3	9·2
Negative	96·3	94·2	89·4
False positive	1·1	0·4	0·7
False negative	0·3	1·1	0·7

Scanning 1 year after mastectomy

The conclusion at the end of the first year must be that the incidence of positive bone scan results is still very low (4·3 per cent) and if those patients with positive X-rays are discounted, then the 'scan only' positive results number only 3 out of 278 (1·1 per cent).

Scanning 2 years after mastectomy

The incidence of positive bone scans at 2 years is 9·2 per cent. However, if those patients with other evidence of metastases at the time of scanning are excluded, then the percentage of 'scan only' positive results is 1·4 per cent. Once again, a very small yield of useful information for a great deal of effort.

General conclusion

Differences in patient selection and methodology are a possible explanation for the widely differing reported incidence of positive bone scans. In Campbell's series, the 'equivocal' group of results were classed as positive, but even without combining these two groups, Campbell found a positive incidence of 26·25 per cent—ten times our figure of 2·3 per cent.

In the Nottingham study (*Table IV*) only patients with primary operable breast cancer under the age of 75 years have been included. The incidence of positive bone scans will be much greater in those with more advanced disease, and possibly also in the elderly. Gerber's patients were all 'recipients of no-cost military medical care' (Gerber et al., 1977). This led those authors to conclude that the low incidence of positive scans in his group (1·8 per cent) was because the patients, by not having to pay directly, were presenting themselves much earlier. Our results are similar to Gerber's and our patients also do not pay for their treatment. Nevertheless, two other British series (Campbell et al., 1976; Roberts et al., 1976) both report a far higher incidence of positive scans.

Citrin et al. (1974) have pointed out the considerable advantages of a gamma camera over a rectilinear scanner. Our recently acquired gamma camera is much preferred to the rectlinear scanner; nevertheless, the results are comparable with both systems. Furthermore, it does not appear that the low number of positive scans is a technical fault. Positive bone scans have been obtained in patients with bone pain from metastatic breast cancer but in whom conventional X-rays were negative. Hence the radiologists can and do diagnose bony metastases on a scan, confirming the presence of metastatic disease in breast cancer.

A further worrying conclusion from this study is the demonstration of how little relevance a positive bone scan result has to the management of the asymptomatic patient. In 1978, Baker wrote '. . . to my knowledge, there is no evidence that the detection and treatment of small asymptomatic bone metastases will necessarily increase either the length, or the quality of survival of patients with breast cancer'.

Although bone scans do detect metastases, it should be stressed that the number of asymptomatic patients with these early lesions is extremely small. Furthermore, each scan costs on average £30 to perform, hence the 773 scans in our series have cost £23 190. Routine bone scanning in breast cancer is increasingly being used throughout the country, but this is difficult to justify when the yield of useful information from the routine use of this investigation is so derisory.

A GENTLER APPROACH TO THE TREATMENT OF BREAST CANCER

Too often, victims of breast cancer must also suffer the unpleasant side effects of combination cytotoxic chemotherapy.

'Nolvadex' offers a gentler alternative, particularly in post-menopausal women with predominantly soft-tissue disease or metastases. Up to 70% of such patients have responded to 'Nolvadex'[1] yet side effects of treatment are far fewer and much less distressing than with cytotoxic chemotherapy or with additive endocrine therapy.[2]

Moreover, a simple oral dosage means that patients may continue with 'Nolvadex' treatment in their own homes.

mightier than the knife

Now there is a practical alternative to surgery for calcium renal lithiasis: long-term prophylaxis with Zyloric.

Zyloric has proved effective in preventing and treating calcium renal lithiasis in patients with raised serum or urinary uric acid.

In a recent trial,[1] 48 patients with hyperuricosuria were treated with Zyloric for an average of 3.88 patient-years. The number of renal stones predicted for this period was 94.9. The actual number of stones formed was 8. Prior to treatment with Zyloric, half of these patients were hospitalised because of stone disease.

A leading article[2] in the *British Medical Journal*, commenting on another clinical paper[3] stated "… the only criterion of success in the treatment of calcium stone disease is total cessation of stone formation. By this criterion, allopurinol (Zyloric) was greatly superior to the placebo."

[1] *Ann. intern. Med.* (1977), **87**, 404. [2] *Brit. med. J.* (1977), **2**, 1302. [3] *J. Urol.* (1977), **117**, 690.

ZYLORIC-300

allopurinol BP Wellcome

stops renal stones starting

Indications: Conditions of excess body urate including gouty arthritis. Prophylaxis of calcium renal lithiasis in patients with raised serum or urinary uric acid.
Dosage: The average adult dose is one Zyloric-300 tablet daily, plus an anti-inflammatory agent or colchicine for at least one month. Dosage should be adjusted by monitoring serum uric acid until the required level is attained. It has rarely been found necessary to exceed 900 mg per day. Children 10-20 mg/kg bodyweight/day.
Contra-indications: None, other than known intolerance to Zyloric. **Precautions:** If Puri-Nethol* (6-mercaptopurine) or Imuran* (azathioprine) is given concurrently with Zyloric, the dose of Puri-Nethol or Imuran should be reduced to one quarter of the usual dose. Caution should be observed in pregnancy. Zyloric is not a treatment for acute gout, but prophylactic treatment with Zyloric may be started at the same time as anti-inflammatory treatment. **Side-effects:** These are usually rare and mostly of a minor nature. They include skin reactions, generalised hypersensitivity, gastro-intestinal disorders, blood and lymphatic disorders. **Presentation:** Zyloric-300* is available as 300 mg scored, creamy-white tablets in packs of 28. Basic NHS cost: £5.96 per pack. PL 3/0092. Also available: 100 mg tablets in bottles of 100. Additional information about Zyloric* (allopurinol) is available on request.

Joint Meetings of the Association of Surgeons of Great Britain and Ireland and the Royal Australasian College of Surgeons, 3–18 February 1979

DURING February 1979 a group of surgeons representing the Association of Surgeons of Great Britain and Ireland attended joint scientific meetings in Australia and New Zealand. This was a unique occasion as the Association had never before held a metting outside the United Kingdom and Eire.

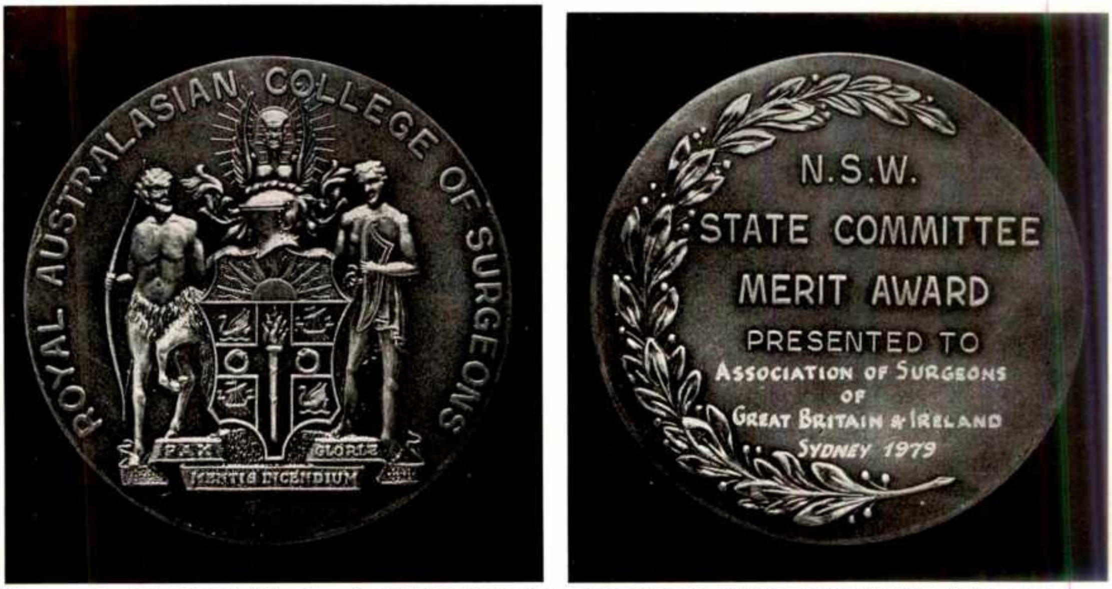
A party of 61, including 20 wives, left Heathrow Airport on the morning of Sunday 4 February, unfortunately 24 hours late due to reputed undercarriage trouble in the Jumbo jet. Following a further delay in Bombay, because of flight-deck computer problems, the party arrived in Perth early on Monday afternoon, after the scientific meeting had already commenced that morning. To enable members of our party to combat jet lag, an amended programme permitted the British papers to be presented the following day.

The joint meeting held on Tuesday and Wednesday 6 and 7 February was at the invitation of the Royal Australasian College of Surgeons in commemoration of the 150th anniversary year of the foundation of the state of Western Australia. The conference took place in the Sheraton Hotel in Perth, being organized by Professor Bernard Catchpole, who was well known to most of the party from his former days in Manchester and at St Bartholomew's Hospital, London. Surgical papers were presented by both Australian and British surgeons, covering various topics on general surgery.

Members of the Association and their wives were generously entertained during our short stay in Perth, and immediately after our arrival on the first evening we enjoyed a steak barbecue at the water's edge at the Royal Perth Yacht Club. Although many members were entertained privately by old friends, on the second evening the majority of our group undertook a delightful sail along the Swan River to Freemantle, the port of Perth, culminating in a seafood repast at the Oysterbed Restaurant.

On the final evening in Perth the conference dinner was held in the Sheraton Hotel, the main speaker being Professor G. Douglas Tracey, Junior Vice-President of the Royal Australasian College of Surgeons, who proposed the toast to the Association of Surgeons. The President of the Association, Mr Alan Birt, CBE, responded and expressed our great pleasure in being present on this auspicious occasion.

The following day the British party left on a 4-hour flight across the deserts of Australia to Sydney for a 2-day scientific meeting which was held in the Wentworth Hotel. This was a joint meeting of our Association in conjunction with the Annual Scientific Meeting of the New South Wales State Committee of the Royal Australasian College. The British party was welcomed on the first morning by Professor John Ham and our great friend, Sir John Lowenthal. The meeting was extremely well attended by the Australian surgeons and, as in Perth, the standard of papers read by both the Associations was consistently high. At the conclusion of the meeting Professor Ham presented the Association of Surgeons with the Medal of the New South Wales State Committee. This Medal is normally presented each year to the author of the best paper given at their scientific meeting, but to mark this historic occasion, it was awarded to the Association of Surgeons of Great Britain and Ireland



Photographs of the Medal of the New South Wales State Committee of the Royal Australasian College of Surgeons.

as a group. The Medal was accepted on behalf of the Association by Mr Adrian Marston, in the absence of Mr Alan Birt who was unfortunately confined to his bed with a virus infection.

The hospitality extended by the Australians in Sydney was exceptional, everyone in the British party being entertained either in a private house or club in in the city of Sydney.

On Sunday 11 February the majority of the British group, together with many of our hosts, spent the whole day on a cruise of the harbour and the numerous attractive bays around which Sydney is situated. Several members were fortunate enough to be able to attend the Sixth Test Match between England and Australia, played at the Sydney Oval. In glorious sunshine the party took great delight in watching the England side bat, but play was drawn to a close rather suddenly at the tea interval because of a hurricane-like storm.

During the final day in Sydney many members visited hospitals in the Sydney area. Mr G. J. Hadfield and the author made a short visit by air to the Royal Australasian College of Surgeons in Melbourne. They were received and conducted around the College by Council Member Professor Richard C. Bennett of Melbourne and by Mr R. Chapman, Secretary of the Australasian College. On the last evening in Sydney the British party, together with our Australian hosts, visited the famous Opera House, dining in the restaurant which overlooks the harbour and Sydney's renowned bridge. We then witnessed a spectacular performance by the Australia Opera Company of Franz Lehar's opera 'The Merry Widow', with Miss Joan Sutherland in the title role. This was a memorable occasion on our final evening in Australia.

On Tuesday 13 February we boarded our Jumbo jet for New Zealand and arrived in Auckland in the early evening. The following day a joint scientific meeting was held at the Royal Hospital, organized by Professor E. M. Nansen, and papers were read by both British and New Zealand surgeons. The remaining two days in New Zealand were taken up mainly by sightseeing and included an unforgettable visit to the Maori village in Rotorua, where we were fascinated by the volcanic hot springs.

On Saturday 17 February, a tired but happy party left on a long non-stop flight to Singapore, spending 24 hours in this far-Eastern centre. During the first evening many of us visited the famous Raffles Hotel, sampling a Singapore gin sling, before partaking of a traditional Chinese meal on the side-walk of Albert Street. On the final day members of the Association enjoyed a tour of the city, plus another Chinese meal, and in the afternoon a cruise around the harbour of Singapore before finally departing for London via Bahrain in the late evening.

This was a memorable stimulating tour, with excellent scientific meetings, magnificent scenery, renewal of old friendships and hospitality without precedent.

A new generation of Micra Titanium Instruments.

Downs Surgical's new range of Micra titanium forceps offers advances in design and quality with a complete choice of delicate tips.

This new generation of Micra titanium forceps incorporates the requests for improvement revealed in a world-wide survey of Micra Instrument users.

Now these improvements are made possible due to our improved titanium technology.

Straight, curved and colibri forceps are available with tying platforms on tying, notched and toothed tips or as plain forceps.

For full details just return the coupon.

Downs Surgical
Simply the best.

Downs Surgical Limited, Church Path, Mitcham, Surrey CR4 3UE England.

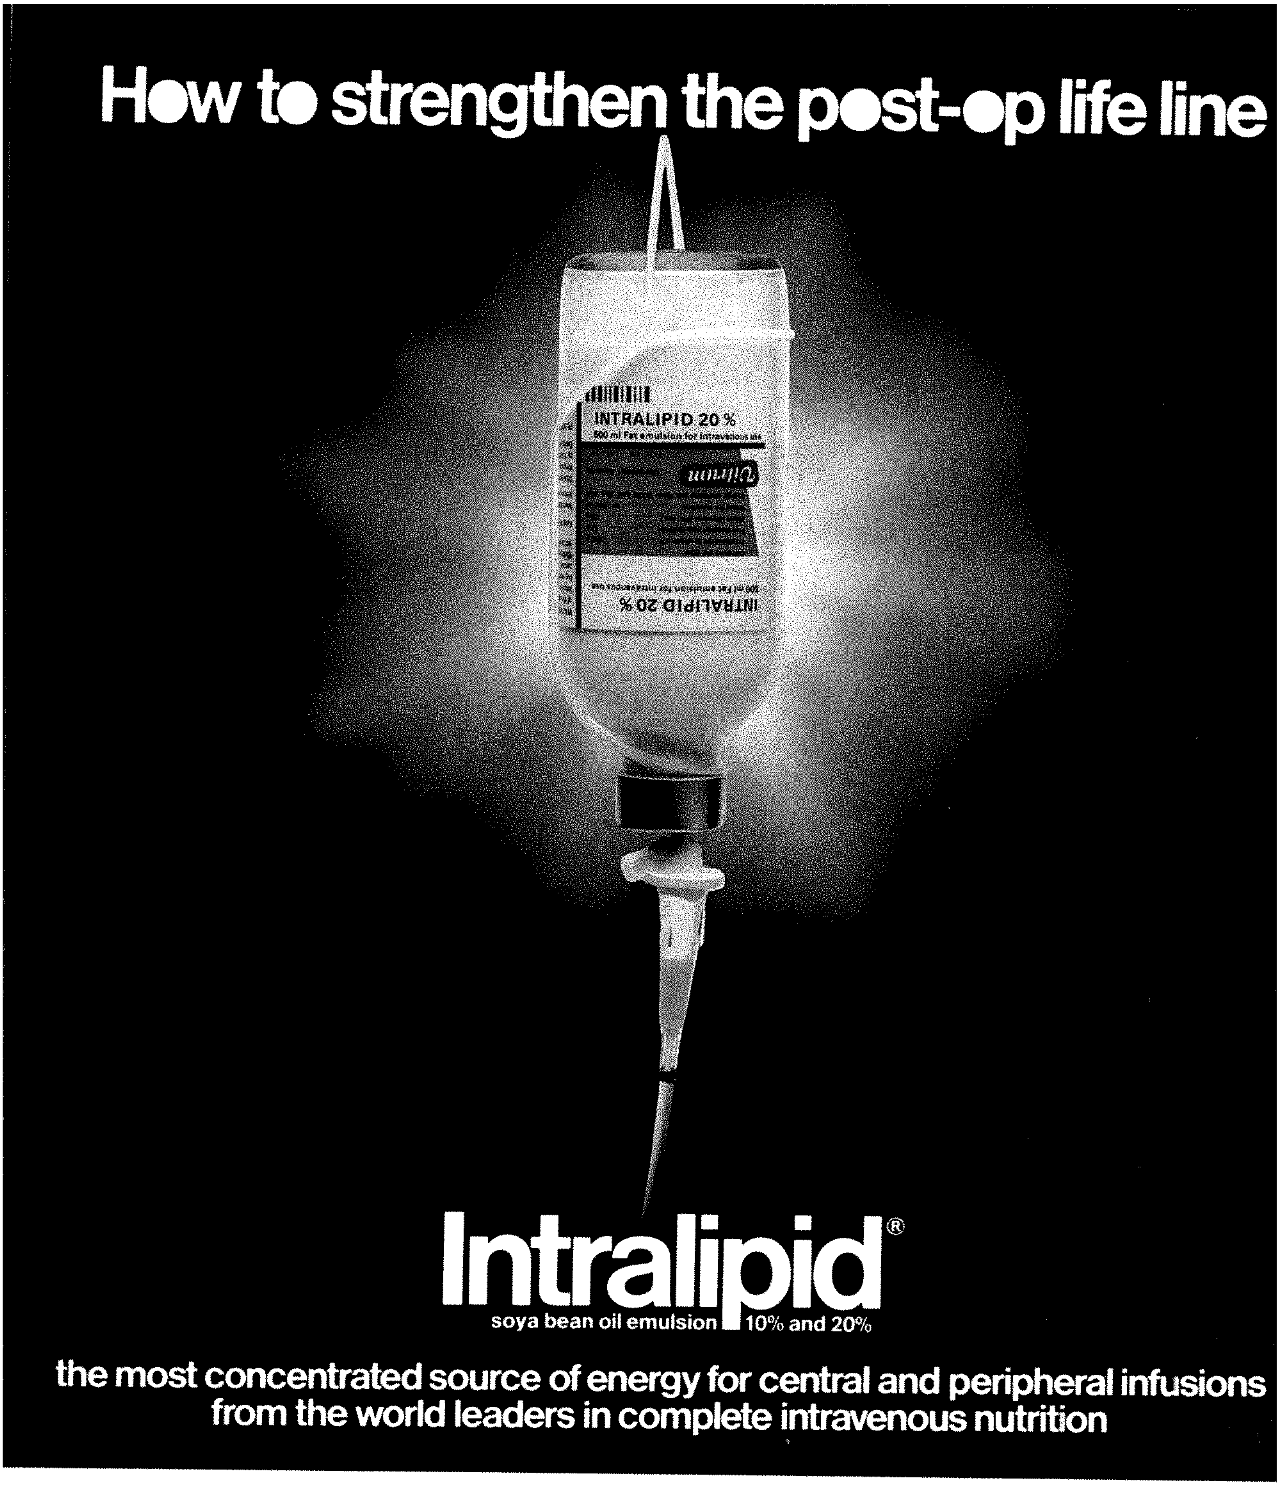
STOL



How to strengthen the post-op life line
INTRALIPID 20 %
500 ml Fat emulsion for intravenous use
Vitrum
Intralipid®
soya bean oil emulsion 10% and 20%
the most concentrated source of energy for central and peripheral infusions
from the world leaders in complete intravenous nutrition

PRESCRIBING INFORMATION

INTRALIPID® 10% INTRALIPID® 20%

Presentation A milky-white oil in water emulsion.

	Intralipid 10%	*Intralipid 20%*
Fractionated soya-bean oil	50 g	100 g
Fractionated egg lecithin	6 g	6 g
Diluted glycerol (Ph. Int.)	12.5 g	12.5 g
Water for injections to 500 ml		

pH c. 7. The solution is sterile and pyrogen-free.

Uses When feeding patients intravenously the possibility of providing a sufficient amount of energy in the form of carbohydrate is limited by such considerations as hypertonicity, hypervolaemia and the tendency to thrombophlebitis. The development of fat emulsions has overcome these problems. Fat has a high energy value (9.3 calories per gram) and by the use of fat emulsion it is possible to provide a high calorie intake in a relatively small fluid volume. Fat emulsions also have a protein-sparing effect when given in conjunction with amino-acid solutions to correct negative nitrogen balance. The intravenous fat emulsion Intralipid is metabolised in the same way and at the same rate as normal chylomicrons. One litre of Intralipid 10% provides 1,100 calories and 1 litre of Intralipid 20% provides 2,000 calories.

Indications Intralipid fat emulsions are indicated in conditions of severe protein depletion requiring also a high energy intake to compensate for excessive loss of calories following trauma, infection, fever, burns, etc.

Dosage and administration Intralipid 10%: 500–1,500 ml daily in conjunction with intravenous amino-acids. For increased caloric requirements Intralipid 20%: 500–1,500 ml daily in conjunction with amino-acids. Intralipid 10% and 20% are administered by slow intravenous infusion. During the first 10 minutes the drip rate should be adjusted to 20 drops per minute and after half an hour this can be adjusted to a final rate of 60 drops per minute. 500 ml of either emulsion should be given in not less than three to five hours on the first day of infusion. On the first day of infusion it is advisable to administer 10 ml Intralipid 10% or 5 ml Intralipid 20% per kg body weight. Subsequently the dose is usually doubled, and when a larger intake is indicated it may be increased to 3 g fat per kg body weight.

Infant dosage Intralipid 10% or 20%: 15–20 ml per kg body weight in 24 hours.

Contra-indications, warnings, etc. Intralipid is contra-indicated in pathological hyperlipaemia and severe liver damage.

Precautions When daily intravenous fat administration for more than one week is indicated it must be ascertained, in order to prevent the development of cumulative lipaemia, that the patient is capable of eliminating the infused fat from the circulation, and this function can be tested in the following manner. In the morning following the first day's infusion, a citrated blood sample is drawn, preferably when the patient is still in a fasting state. The blood sample is centrifuged at 1,200–1,500 rpm. If the plasma is then strongly opalescent or milky, further infusion should be postponed. In the great majority of cases, plasma is completely clear 12 hours after the conclusion of an infusion of 2 g fat per kg body weight (corresponding to 20 ml of Intralipid 10% or 10 ml of Intralipid 20% per kg body weight). This test should be repeated at weekly intervals.

Pharmaceutical precautions Store at a temperature between 4°C and 8°C, and do not use after the date of expiry indicated. The contents of each bottle are for a single infusion and any residual emulsion should be discarded. No drugs should be added to Intralipid prior to or during infusion.

Legal category No legal restriction on sale or supply.

Package quantities *Intralipid 10%*: 100 ml and 500 ml. *Intralipid 20%*: 100 ml and 500 ml.

Further information Nil.

*Constitute the Editorial Committee

Whilst every effort is made by the publishers and editorial committee to see that no inaccurate or misleading data, opinion or statement appear in this Journal, they wish to make it clear that the data and opinions appearing in the articles and advertisements herein are the responsibility of the contributor or advertiser concerned. Accordingly, the publishers and the editorial committee and their respective employees, officers and agents accept no liability whatsoever for the consequences of any such inaccurate or misleading data, opinion or statement.

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, John Wright & Sons Ltd, Broadmead House, 21 Panton Street, London SW1Y 4DR.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the journal unless rights are reserved before publication.

Business communications should be sent to *John Wright & Sons Ltd, British Journal of Surgery, Bristol BS8 1EX.* Remittances are payable to the *British Journal of Surgery.*
Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

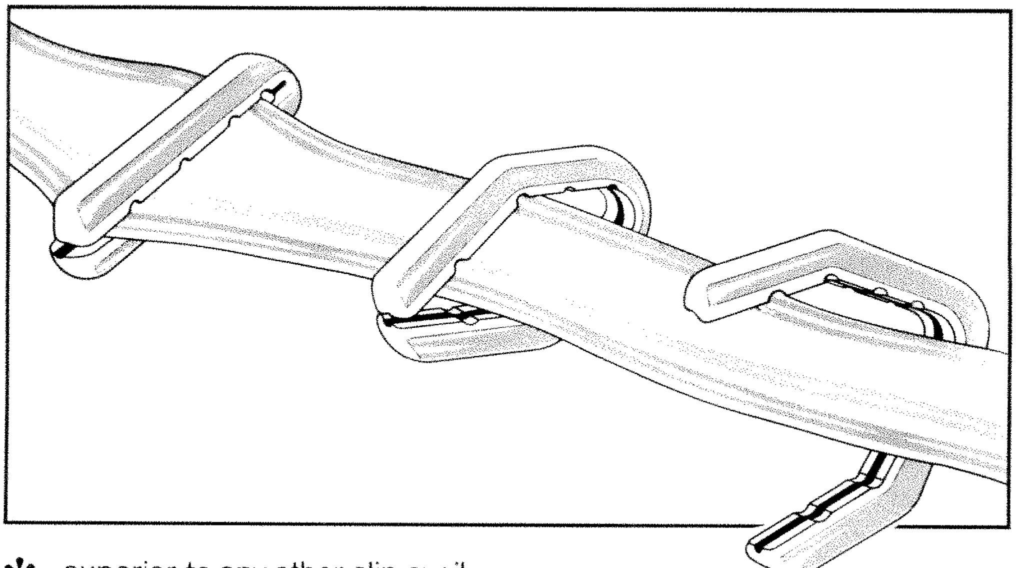
Manuscripts
The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. The abstract must be complete in itself, outlining the aim, results and conclusions of the paper. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations
It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978: **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors*. London, Pitman, 1978.

References
In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus*. Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).

Weck® Hemoclips®
Surgical occlusion proven in over 12 years' use



- * superior to any other clip available will not slip off blood vessel; allows partial occlusion if necessary
- * routinely used in more than 40 different surgical procedures
- * pre-formed to direct pressure uniformly in the applier-true parallel closure without scissoring
- * distal end closes first to encompass all the vessel
- * available in four sizes

Hemoclip closure:
Left is the clip closed, providing a tenacious yet hypotraumatic grip.
Centre is the partially closed clip forming a ring. Right is the open clip; magnifying the longitudinal and transverse grooving-a milled, grooved surface that grips securely without slippage.

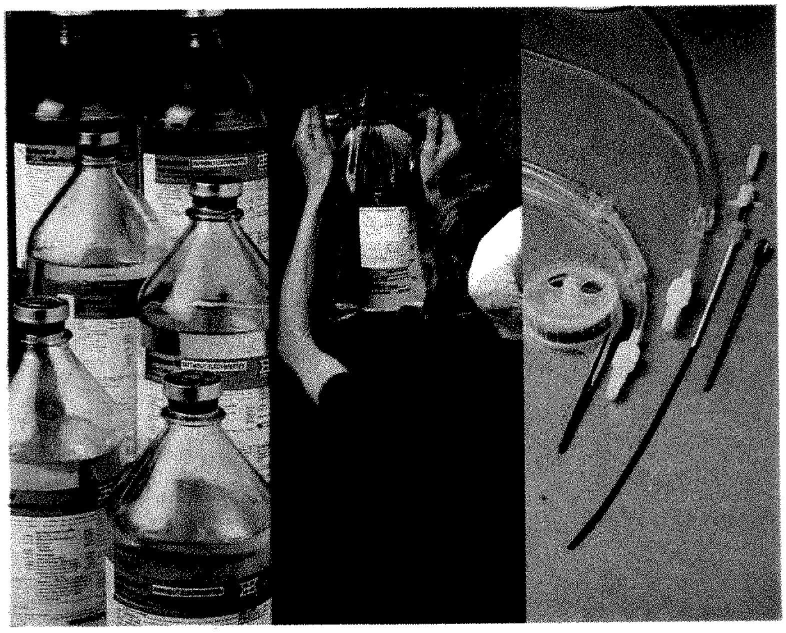
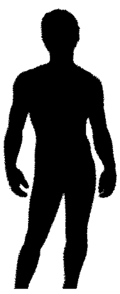
Starvation only makes things worse

Protein calorie malnutrition has been shown to result in poor wound healing and the disruption of anastomoses[1]. It is also associated with diminished resistance to infection[2]. Severely ill patients generally require special nutritional support[3] and, when gastrointestinal function is impaired or absent, parenteral nutrition is the only practical way to provide it. The Travenol parenteral nutrition system is a sensible answer to most intravenous feeding problems. It includes Synthamin amino acid solutions. Non-protein calorie sources. Electrolytes. Peripheral and central venous catheters. Specially designed sets. And 3-litre Viaflex® containers for the sterile compounding of regimens in pharmacy and their non-air-dependent administration on the ward.

Travenol has the sensible answer to parenteral nutrition–because Travenol thinks things through.





Travenol makes sense of Parenteral Nutrition

Synthamin

Presentation
Synthamin injections are sterile, non-pyrogenic solutions of essential and non-essential L-amino acids, provided with or without electrolytes. Synthamin 7S also provides calories as Sorbitol.

Indications
Parenteral nutrition.

Administration and Dosage
For intravenous administration.
An associated source of non-protein energy should be administered of not less than 0.75MJ (180 Cal.) per gram of nitrogen administered. Dosage depends on patient's metabolic requirements and clinical response.

Contra-indications
Severe liver disease. Solutions with electrolytes are contra-indicated in renal failure.

Precautions
As with all hypertonic solutions, vein irritation may occur.
Do not administer unless the solution is clear and container is undamaged.

Availability
Synthamin 7S (PL 0116/0043) 500ml £4.83.
Synthamin 9 (PL 0116/0054) 500ml £6.00.
Synthamin 9 without electrolytes (PL 0116/0067) 500ml £5.65.
Synthamin 14 (PL 0116/0055) 500ml £8.00.
Synthamin 14 without electrolytes (PL 0116/0068) 500ml £7.65.
Synthamin 17 (PL 0116/0056) 500ml £9.80.
Synthamin 17 without electrolytes (PL 0116/0069) 500ml £9.45.

New for Urostomy!

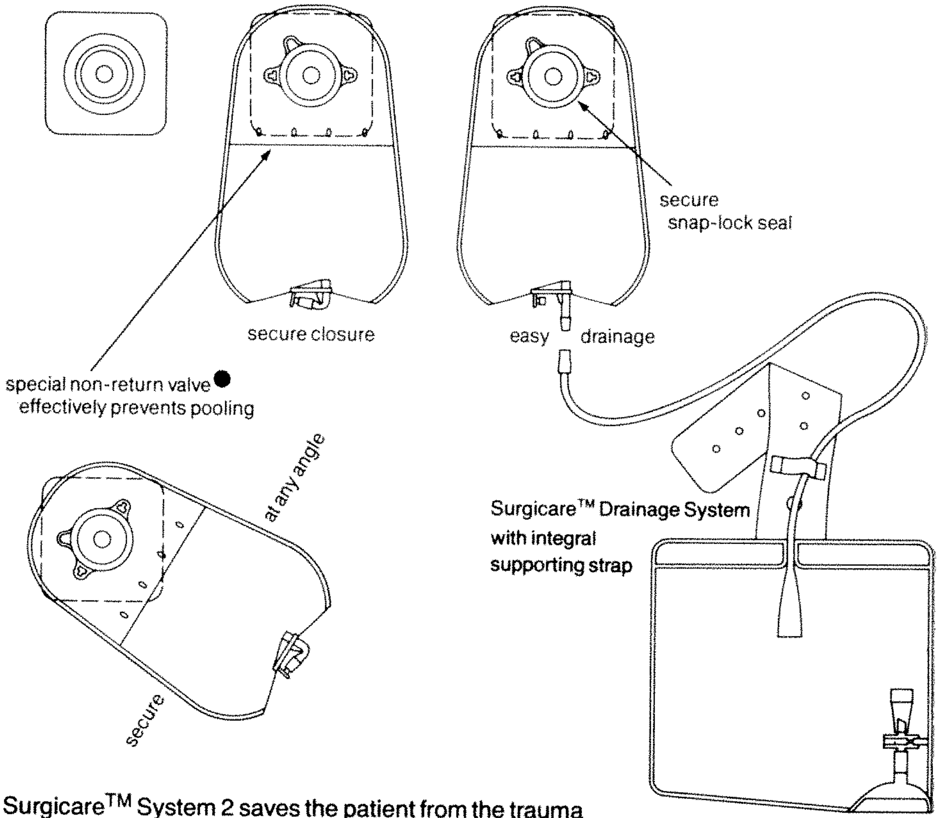
a new standard of comfort and security

SURGICARE System 2

Trademark

Stomahesive™ Flange
the best in skin care

Urostomy pouches simply snap onto the Stomahesive™ Flange



Surgicare™ System 2 saves the patient from the trauma of peeling off adhesive bags. The Stomahesive™ Flange can be left on the skin undisturbed for several days whilst the pouches are replaced as often as necessary. It makes possible a leak-free attachment of appliances to the skin thereby providing a unique degree of comfort free of irritation and soreness often associated with ordinary adhesives. Surgicare™ System 2 takes full advantage of these benefits which are particularly evident in the management or urostomies.

● The non-return valve permits easy access of urine to the lower part of the pouch and efficiently prevents the return of urine to pool in the area of the stoma thus the Stomahesive™ wafer is protected from the breakdown effects of urine and remains secure and leak-free for several days.

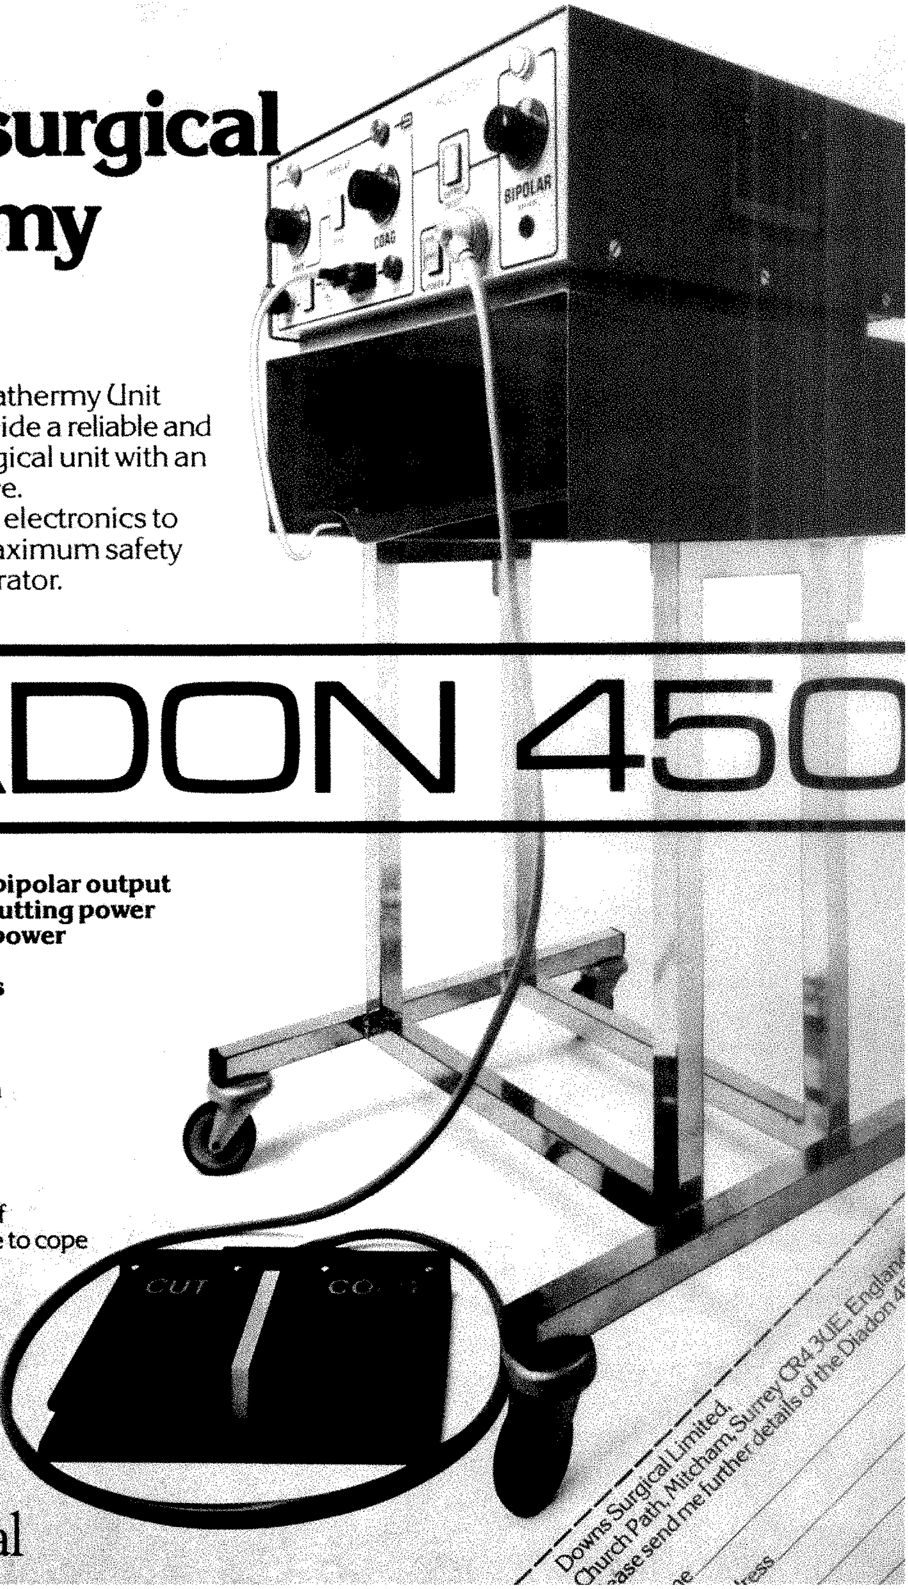
Diadon 450. A New Electrosurgical Diathermy Unit.

The New Diadon 450 Diathermy Unit has been created to provide a reliable and simple to use electrosurgical unit with an outstanding performance.
The unit utilises modern electronics to provide conditions of maximum safety to both patients and operator.



DIADON 450

- ☐ **Powerful unipolar and bipolar output**
  400 watts continuous cutting power
  125 watts coagulating power
- ☐ **Blending**
- ☐ **Audible indicator tones**
- ☐ **Plate monitors**
- ☐ **Low output voltage**
- ☐ **Isolated outputs**
- ☐ **Simplicity of operation**
- ☐ **Pneumatic footswitch**

Diadon 450 is suitable for continual use in the busiest of operating theatres and is able to cope with all surgical specialities.

Operative Surgery – Third Edition
Fundamental International Techniques
General Editors: Charles Rob, Rodney Smith (Lord Smith of Marlow) and Hugh Dudley

Plastic Surgery
John Watson, FRCS(Ed), FRCS(Eng)
Robert M. McCormack, MD

This new edition of Plastic Surgery has been almost entirely rewritten by a team of international authors, each an acknowledged expert in his speciality. The text has been expanded to allow each contributor to describe more fully the principles and practice of his operative technique.

Not only are all the fundamental techniques of plastic surgery included – techniques which can be extended to most types of conditions, including the increasingly treated 'aesthetic' problems – but new sections on such specialities as genito-urinary, microvascular and microneural surgery have been added to make this edition complete and up-to-date.

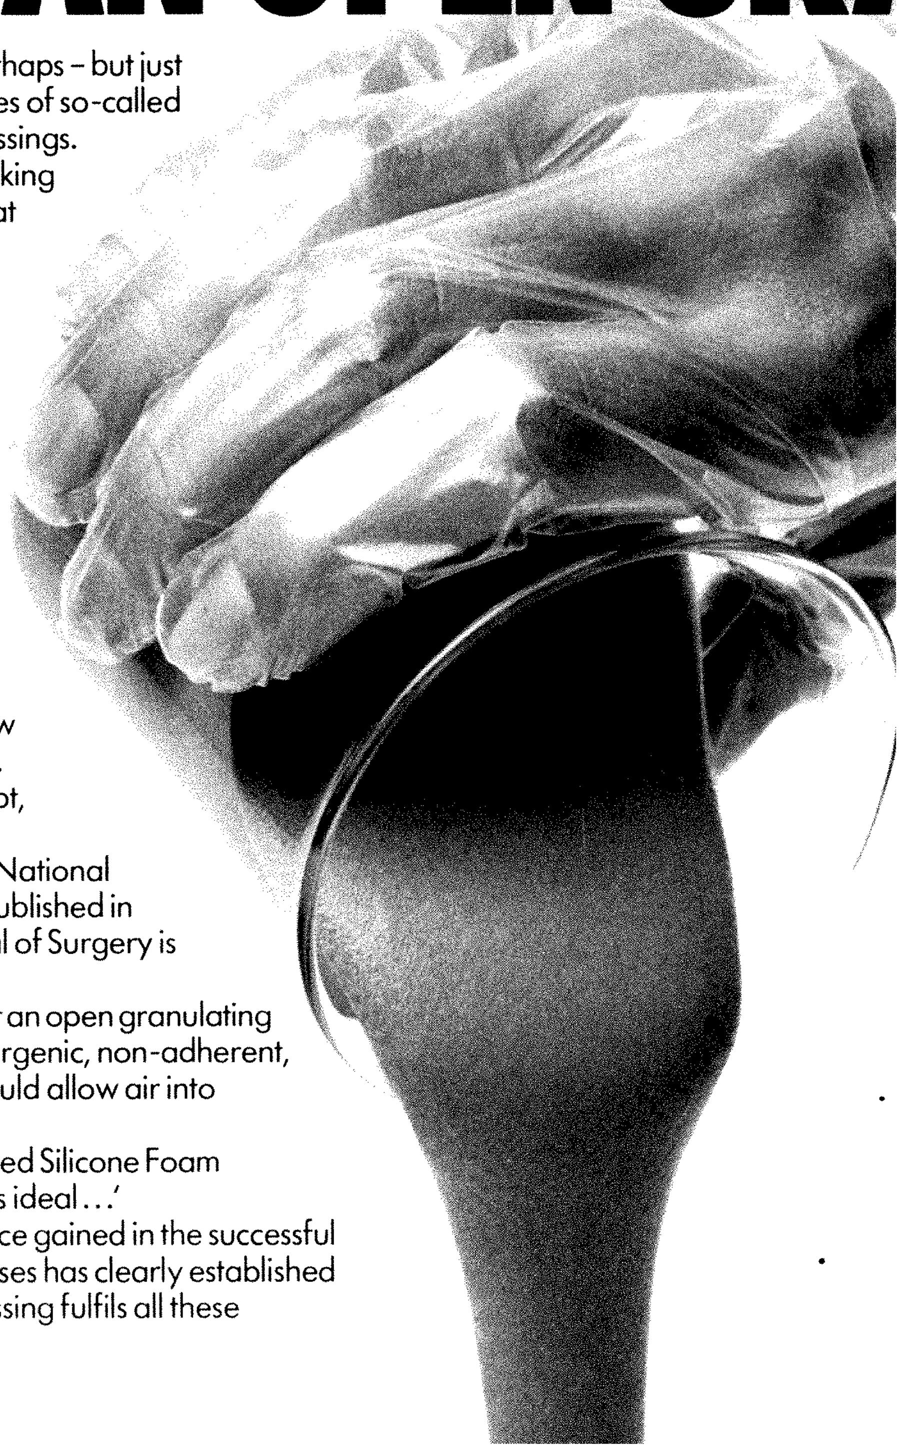
THIS IS A DRESSIN
INTO AN OPEN GR



Unconventional, perhaps – but just consider the disadvantages of so-called 'conventional' wound dressings.

Standard gauze packing requires skilled changing at frequent intervals – with dirty or infected wounds this can be three or more times a day.

Gauze packing provides inadequate drainage and poor air circulation: as it sticks to the newly formed tissue, it is uncomfortable, often painful to remove.

Now, consider the alternatives offered by new SILASTIC® Foam Dressing.

The following excerpt, from a report written by researchers at The Welsh National School of Medicine and published in 1977 by The British Journal of Surgery is of particular interest:

'An ideal dressing for an open granulating wound would be non-allergenic, non-adherent, slightly absorbent and would allow air into the wound.

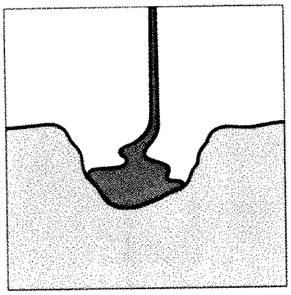
SILASTIC® Polymerised Silicone Foam Elastomer approaches this ideal...'

Since then, experience gained in the successful treatment of over 1000 cases has clearly established that SILASTIC® Foam Dressing fulfils all these requirements, and more.

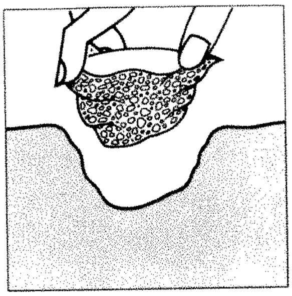
SILASTIC® is a registered trademark of Dow Corning.

BEING POURED NULATING WOUND

The application of SILASTIC® Foam Dressing. This can be easily demonstrated by pouring the elastomer foam base and catalyst mix into the wound as shown, and allowing to cure for some 2–3 minutes. The foam expands rapidly to approximately 4 times its original volume, conforming exactly to the natural configuration of the wound, while becoming spongy to the touch.



Simply pour the Foam Dressing into wound and allow to cure for 2–3 minutes.



The cured dressing can be removed and replaced at will.

This in itself is of considerable benefit to the patient since pressure is thus distributed more evenly across the wound surface, with the dressing retained in place by standard, non-allergic tape for much-improved patient comfort.

Most patients are able to resume their normal occupations much sooner after post-surgery treatment with Foam Dressing than after treatment with conventional dressings.

Most significant of all perhaps is the dramatic decrease in patient trauma normally associated with wound dressing renewal.

Any discomfort experienced when renewing SILASTIC® Foam Dressing is so minimal as to positively encourage frequent cleansing of the wound, enabling the patient to conduct his own wound management programme, in his own home, with little or no skilled nursing attention required.

After thorough cleansing, the dressing is simply repositioned in the wound by either nurse or patient until such time as the healing process necessitates renewal of the dressing (every 5–7 days, on average).

This frequent cleansing, combined with the perfect drainage and biologically-inert construction of the dressing itself has resulted in the elimination of wound infection, a marked tendency towards faster healing and a clear advantage over conventional wound management. Cases to date include pilonidal sinus wounds, perineal wounds, conservative surgery for diabetic gangrene, sacral bed sores, abdominal wall wound breakdown and skin grafting donor sites.

Your Dow Corning representative will be glad to discuss them with you in more detail and to demonstrate new SILASTIC® Foam Dressing to you in your own office. Telephone: 0734 596888, or contact Dow Corning direct.

Gastric reduction for morbid obesity: technique and indications

A. E. KARK AND M. BURKE*

SUMMARY

The results of gastric reduction for obesity in 12 patients are described. Emphasis is laid on preoperative weight loss, using jaw wiring in 9 patients. The successful outcome of the operation was found to depend on the formation of a small gastric pouch and a narrow gastro-jejunal anastomosis. A constant-sized pouch was achieved by forming the pouch around a 100-ml silicone balloon devised for the purpose. Postoperative results were good in 7 patients, partial success was achieved in 3 patients and there were 2 failures.

It is concluded that the procedure will produce successful results provided that a small proximal pouch with a narrow outlet is fashioned in motivated and psychologically well-balanced patients.

MORBID obesity is commonly defined as a body weight at least twice that predicted for a given height, but even an excess of adipose tissue of 40 kg is usually socially and physically disabling and potentially lethal. Many seriously overweight people require medical help and surgical intervention is increasingly being involved.

The currently popular surgical operation is one or other refinement of a small intestinal bypass procedure (Scott et al., 1971; Payne et al., 1973). However, in about half the patients, the consequences are marked metabolic disturbances, diarrhoea or hepatic dysfunction (Alden, 1977; Baddeley, 1977; Buckwalter, 1977). This is, for many, intolerable and is often unacceptable in terms of late mortality.

An alternative method which depends on mechanical reduction of stomach capacity has been pioneered by Mason (Mason and Ito, 1967; Mason et al., 1975) and is called gastric bypass. We have used this procedure, which we prefer to call gastric reduction, and present our experience of the past 4 years. The indications for its use and our modifications of the technique are described in detail.

Indications

Patients considered for operation are those who have been subjected to intensive investigation and prolonged medical treatment, in and out of hospital, but who regain weight. Before surgical intervention, patients must have undergone:

1. Thorough investigation which has excluded any endocrine cause of obesity.
2. Intensive controlled hospital and outpatient dietary regimens which have subsequently failed to maintain weight loss.
3. A period of teeth wiring with an 800 kcal liquid or soft diet maintained until the weight is steady and as close to ideal as can be achieved or, alternatively, for as long as the patient is able to tolerate this treatment.

The last requirement is necessary for three reasons. First, it tests determination and perseverance, thus selecting highly motivated patients, and eliminates the psychologically disturbed patient. Secondly, it ensures that gross obesity will have been substantially reduced, thus simplifying the operation and reducing post-operative morbidity. Thirdly, it allows time to explain to the patient the risks of the operation and the effects of the procedure.

Patients and methods

Operative technique

A long vertical midline incision is used from 2·5 cm above the xiphisternum to 5 cm below the umbilicus (*Fig.* 1). The xiphisternum is either removed or split. To form the proximal stomach pouch the upper third of the greater curvature is cleared of vasa brevia and attachments up to the hiatus and abdominal oesophagus (*Fig.* 1). It is essential to mobilize the upper greater curvature so that the high division of the stomach can be performed largely out of the abdomen and not in a relatively inaccessible, deep subdiaphragmatic cavity. The lesser curvature is exposed by making a two-finger opening in the lesser omentum about 6–8 cm from the hiatus, close to the gastric wall, without dividing vessels or vagi. Preservation of the right vagus is necessary to avoid retention in the large distal remnant, and the blood supply of the proximal remnant is ensured by the intact left gastric artery.

The proximal gastric pouch must not exceed 100 ml in capacity. The final size is difficult to estimate, and measurement by finger, eye or ruler along the curvatures is inaccurate and imprecise. This constant-sized proximal remnant is achieved by means of a sterilizable, silicone rubber, plastic sphere (Silgard 186, Dow Corning) (*Fig.* 2) which has a radius of 3·1 cm. The sphere, attached to a rigid 20-cm handle for ease of manipulation, is placed against the diaphragm over the outside of the upper stomach to outline the size of the pouch. The lesser and greater curvature just beyond the lower part of the sphere are picked up with Babcock's forceps and then the stomach is transected between soft clamps so that the upper pouch remains slightly larger than the sphere. The cut edges of

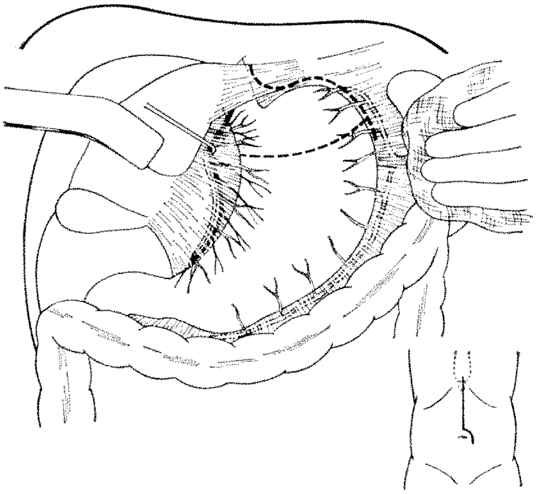

Fig. 1. Small proximal gastric pouch mobilized by division of vasa brevia and attachments right up to the abdominal oesophagus. Note: careful hand retraction of spleen; preservation of right vagus and left gastric artery arcade. *Inset*, Long upper midline incision extending from xiphisternum to below umbilicus.

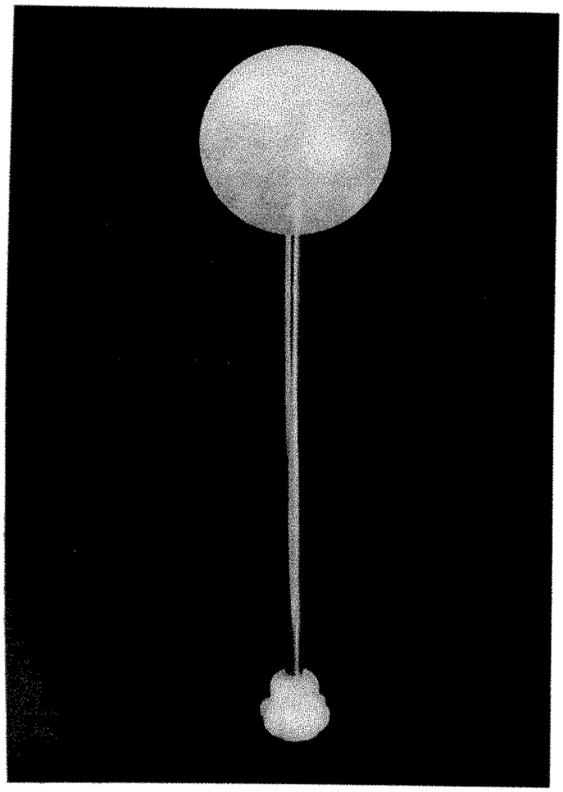

Fig. 2. Plastic sphere of volume 100 ml with rigid handle attached.

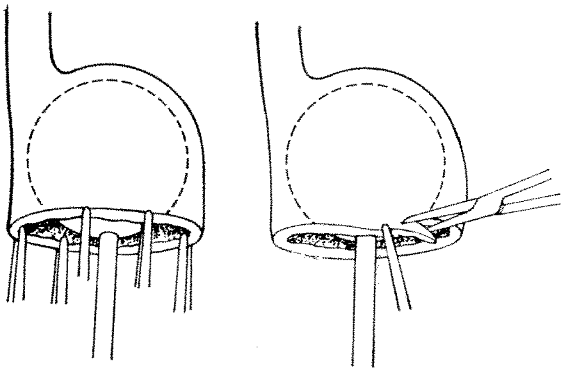

Fig. 3. Accurate assessment and tailoring of upper gastric pouch using a plastic sphere with a radius of 3·1 cm which provides a volume of about 100 ml. Note: trimming of redundant stomach wall so that closure can be snugly made around the sphere.

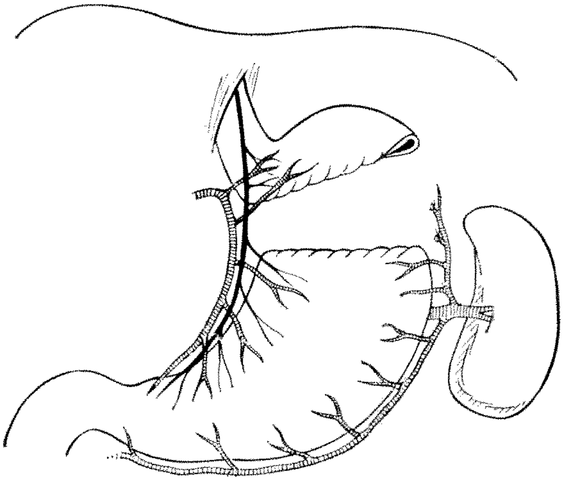

Fig. 4. Completed separation of upper gastric pouch with two-layer closure of all but a 12-mm opening measured by a 12-mm Hegar dilator.

the upper pouch are then picked up by a series of Allis forceps. The sphere is now inserted into the cavity of the upper pouch, pushed against the diaphragm and the lower rim pulled over the sphere (*Fig.* 3). The excess upper pouch is trimmed off so that the pouch, after suturing, will be of the same capacity as the sphere. The sphere is withdrawn and the pouch closed, leaving a small opening on the greater curvature just sufficient to admit a 12-mm Hegar dilator. Closure of the large distal stomach remnant is effected by standard inner continuous catgut and outer continuous silk sutures (*Fig.* 4).

Anastomosis of the proximal pouch to the jejunum is fashioned in the same way as a Polya–Hofmeister anastomosis using either a short retrocolic jejunal loop or an antecolic loop.

The size of the gastrojejunal stoma is critical. It must not be greater than 10 mm. The gastrojejunal stoma is therefore made with interrupted inner catgut and interrupted outer silk layers so as to minimize any further contraction of the opening during its construction. Before completing the inner layer, a Hegar dilator is inserted, and after being adjudged to fit snugly, the outer interrupted silk is placed (*Fig.* 5 inset). Next, the jejunum distal to the stoma is attached to the closed proximal pouch in the fashion of a Hofmeister valve. The distal stomach pouch is then tacked by three interrupted silk sutures to the anterior wall of the proximal segment, or to the diaphragm, so as to avoid possible rotation (*Fig.* 5).

If gallstones are present a cholecystectomy is performed. Drainage of the peritoneal cavity has not been necessary. Closure of the abdominal wall is effected by continuous monofilament nylon in one layer but the subcutaneous tissues and skin are left open with skin sutures in place for approximation after 4 days. The open wound is packed with Vaseline gauze and dry dressing.

A nasogastric tube is placed in the proximal gastric pouch, care being taken not to pass it through the stoma.

Patients

In the past 4 years 12 patients have been submitted to operation (*Table I*). Their ages ranged from 25 to 39 years except for one woman of 56 years accepted because of osteoarthritis of her hip. There were 7 women and 5 men. Nine patients were obese since childhood or early adolescence but 3 of the 7 women became obese after their first pregnancy and gained weight after each subsequent pregnancy.

All patients were socially embarrassed to a degree that caused them to remain housebound. Some were unemployable, 9 were dyspnoeic after walking short distances and 4 had marked orthopaedic deformities, mainly in the form of weight-bearing strain. All had a degree of psychological disturbance, 2 with episodes of depression requiring hospitalization. Six of the patients had severe domestic problems. Those who regained weight after gastroplasty and those who were treatment failures had recurrent domestic crises of a serious nature. All patients had undergone repeated dietary treatment with medical supervision. Jaw wiring was undertaken in 9 patients. Of the remaining 3 patients, 2 were unsuitable for wiring and 1 refused the procedure. The duration of the jaw wiring ranged from 2 to 24 months (2, 5, 5, 6, 6, 7, 9, 13, 14+10 months). In 3 patients the delay after jaw wiring before gastric reduction was undertaken was too long, and their weight increased in the intervening period from 76 to 106 kg, 71 to 105 kg and 101 to 117 kg respectively.

Patients did well in the postoperative period. One required immediate reopening for a suture line bleeding point. Three vomited in the first week until they became accustomed to the drastic limitation in intake. One patient started vomiting again 3 weeks after discharge but reassurance, fluids for 2 days and care with subsequent solids restored her to normal.

Seven of the 12 patients had a good result (*Table I*). Five of these are now close to or below their ideal weight and find little difficulty in maintaining this level. Two patients operated on more recently are both steadily losing weight, albeit slowly. None has experienced vomiting after the first few weeks and all are aware of their decreased stomach capacity. None has had metabolic problems. The haemoglobin and serum B12 levels have remained within normal limits. Dumping has not been encountered. Bowel action has been within normal limits (1–2 times a day, stools being firm). General health has been well maintained and, encouragingly, the domestic situations of the patients have stabilized.

Three patients may be regarded as partial successes: they still exhibit considerable social and psychological disturbance. Nevertheless, a year or more after the procedure they are substantially below their previous maximum weight. In one case the reduction was from 165 to 120 kg (ideal weight 86 kg), in the second the loss was from 138 to 113 kg (ideal weight 78 kg), while in the third patient the loss has been from 108 to 95 kg (ideal weight 64 kg). Thus, while still approximately 50 per cent above their ideal weight, they have lost enough to give them a subjective feeling of improvement.

Two patients were deemed failures. One, a young woman who had been obese from early childhood and who had undergone psychotherapy without success, had a gastroplasty in October 1974 when she weighed 103 kg. Although she reduced her weight to 95 kg she regained her preoperative weight within a matter of months and finally reached 119 kg, at which point—nearly 22 months later—she had the gastroplasty converted to a gastric reduction procedure. Her present weight is 110 kg, this being marginally less than her preoperative weight, but she is a determined and persistent eater. She had jaw wiring for 7 months prior to the first operation, losing 27 kg. She tolerated this manoeuvre, but, in retrospect, she

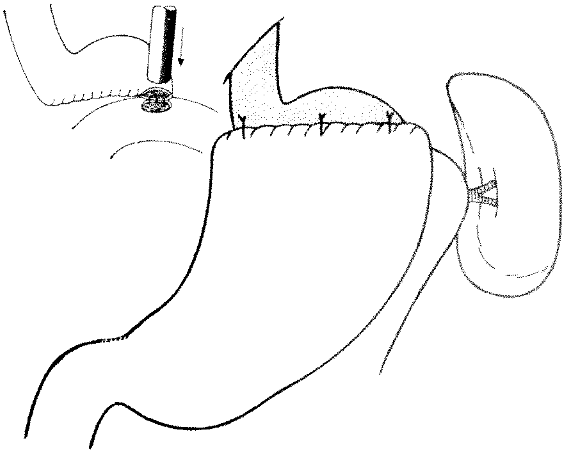

Fig. 5. The large distal pouch after closure by continuous inner catgut and continuous outer silk is finally attached by three to four interrupted silk sutures to the anterior surface of the upper pouch so as to avoid twisting. *Inset*, Accurate construction of the gastrojejunal anastomosis. M	32	93	207	—	—		Bypass	6	Good

IMF, Maxillomandibular fixation.

was so disturbed psychologically and so unstable in her domestic situation that she should not have been accepted for the surgical procedure.

The second failure was a young man of 26 who had gradually gained weight since late adolescence and who had made many unsuccessful attempts to diet both at home and in hospital. He agreed to jaw wiring, which was maintained for 9 months, during which time his weight fell from 119 to 71 kg. In June 1977 a gastric reduction operation was performed; however, on the third postoperative day, he demanded adamantly that the procedure be reversed. Despite persuasive medical advice, his insistence was acceded to, his weight as a result of retching and resistance to any food intake being 68 kg. The reversal procedure was technically satisfactory, but he developed peritonitis on the ninth postoperative day due to a leak at the suture line. After three subsequent operations he finally died.

Discussion

Only in the past decade has surgery been considered in the treatment of morbid obesity. The need has arisen because of the increasing numbers of obese people in Western society and their frequent referral to hospital for complications of their condition.

The more serious complications of gross obesity affect multiple organ systems and usually substantially lessen the life span. There is a very significant increase in the incidence of diabetes, hypertension and stasis ulceration (Buchwald et al., 1973). Orthopaedic problems usually affect hips, spine and knees, reflecting the abnormal weight carried by these joints; in older patients a moderate weight loss of about 24 kg can provide symptomatic relief.

Psychological problems are always present to a greater or lesser degree. There are few, if any, of these patients who have not had recurrent bouts of depression, and suicide attempts are not rare. It is important to exclude patients who have more serious manifestations, including overt psychoses, mental and social instability and unstable domestic situations.

People with moderate degrees of obesity often seek the help of dieting clubs. Only about a quarter of those who diet lose more than 9 kg, and fewer than 5 per cent lose as much as 18 kg. Drugs unfortunately can offer little, and cannot, at present, improve on the results of dietary control.

Because prolonged voluntary reduction of food intake in the obese will produce little if any long term weight loss (Bray et al., 1976), the use of maxillomandibular fixation has been evaluated (Rodgers et al., 1977; Fordyce et al., 1979). This extreme manoeuvre to limit calorie intake has proved technically feasible. In motivated patients it is acceptable and is a most effective method of achieving weight reduction.

We have used the interdental wiring method of maxillomandibular fixation (Fordyce et al., 1979) rather than metal cap splinting (Wood, 1977). Intensive dental care and continuing dental hygiene are necessary. Vomiting has not proved a problem and there has been no damage to the teeth or periodontal tissues. In our patients the average weight loss was 28·8 kg and the average duration of wiring was 8·6 months, results almost identical to those of Rodgers et al. (1977), who reported an average weight loss during 4–12 months' (8·5 ± s.d. 4·3) treatment of 29·3 kg (± s.d. 10·7 kg) in 17 patients. However, the relapse rate after unwiring is practically 90 per cent. Therefore, we have advised operation as soon as the patient begins to regain more than 3–4 kg above his/her best post-wiring weight.

The introduction of a small bowel bypass operation in 1963 and its subsequent modification has been followed by the recognition of the high incidence of late complications (O'Leary et al., 1974; Passaro et al., 1976; Wands et al., 1976; Alden, 1977; Baddeley, 1977, Buckwalter, 1977; Griffen et al., 1977; Parfitt et al., 1978). These, consisting of diarrhoea, fatty liver infiltration, renal stone, osteomalacia and polyarthritis, will in varying degrees affect nearly 50 per cent of patients. The extent of the ensuing morbidity constitutes in some surgeons' view a hazard sufficient to cause them to abandon the procedure (Alden, 1977; Buchwald, 1977; Griffen, 1977).

Although the weight loss produced by small bowel bypass is believed by some to be due to malabsorption of food (Mason et al., 1975), recent balance studies have shown that the main cause is reduced dietary intake (Woodward et al., 1975; Pilkington et al., 1976). Therefore, the alternative procedure of reducing the size of the stomach introduced by Mason (Mason and Ito, 1967), and with which he has extensive experience, appears promising. Recently Alden (1977) has modified the procedure by using an automatic stapling instrument for closure of the distal stomal pouch and for performing the gastrojejunal anastomosis. Both these manoeuvres substantially reduce the operating time. With this evidence and increasing support from other surgeons (Alden, 1977; Buckwalter, 1977; Gomez, 1979), we have adopted this principle in operating on a selected group of morbidly obese patients.

There are two methods of reducing the capacity of the stomach and therefore dietary intake. The first, a gastroplasty, consists of a nearly complete division of the stomach into an upper small segment and a lower larger one, the opening being the final 2 cm of undivided stomach. In 4 patients whom we have treated by gastroplasty there was an initial weight loss of 10–15 kg but after 6 months all of them had stabilized their weight at an insufficiently low level or had begun to regain weight. We have therefore abandoned this technique. However, Gomez (1979) has reintroduced this method using an automatic stapler without the need for division of the stomach, with a purse string of nylon around the newly fashioned stoma to prevent later enlargement. He has preferred this method in a series of 300 patients.

The second method, that of gastric reduction (or 'gastric bypass'), consists of a complete division of the stomach high in the fundus to separate a small proximal pouch from the remainder of the stomach which is left *in situ*.

It became clear early in this series that the procedure requires precision and that the margin of error in fashioning a reduced gastric pouch is small. If the size of the pouch is much smaller than 75–100 ml the first few months may well be intolerable, and even with some adaptation, later existence miserable. If the capacity is greater than 100 ml, even by a small amount, a pouch is left which accommodates very early to a large volume of food without patient discomfort.

In order to standardize the size of the upper pouch, the plastic sphere was introduced. Even this is not without error, since the capacity of the stomach is determined not only by a varying amount of stretch of the gastric wall but also by motility and emptying time of the pylorus. Thus, the size of the stoma is important. It must be small so that determined eating is prevented not only by the size but also by slow emptying. On the other hand, it must not be less than 8 mm otherwise partial obstruction and persistent vomiting will occur. As there is always some late contraction by 10–20 per cent, it is important to limit the narrowing of the stoma during construction by means of carefully placed interrupted inner and interrupted outer sutures. There should be not more than six sutures on both the anterior and posterior surfaces, each suture being about 2 mm apart. Early X-ray studies before leaving hospital show that a narrow 4–6 mm opening due to postoperative oedema is present. After some weeks this widens to about 10 mm.

After 6–12 months the new small stomach learns to adapt to small, well-spaced meals and the major bar to continuous nibbling and snacks is the rapid feeling of fullness that patients learn to dislike. Regular exercise on a daily basis must be insisted upon as a part of the postoperative therapy. High protein diets should be prescribed.

Long term results reported by Mason et al. (1975) can be summarized as a weight loss of 50 kg or more in one-third of patients, 25–50 kg in a further third and less than 25 kg in the remaining third. The average weight loss at 5 years is approximately 36 kg. In both Alden's (1977) and Buckwalter's (1977) series—each being a comparative study of the effects of intestinal and gastric bypass—weight loss was achieved at about the same rate, although the loss is greater and more predictable after gastric bypass. After both procedures at least 75 per cent of excess weight will be lost within 2 years and the younger and more active the patient, the greater the loss. However, it is possible to 'outeat' a gastric bypass by determined drinking of high calorie drinks, whereas this cannot be achieved after jejunoileal bypass. The weight loss is maximal during the first 6 postoperative months (10–20 kg) with a further loss of 5–10 kg up to the first year (Mason et al., 1975). Thereafter there is usually a slight further loss or the weight stabilizes. Thus, in general a loss of at least 75 per cent of excess weight can be expected in the first 2 years.

In a series of nearly 400 gastric bypass operations (Printen and Mason, 1977) a 2·8 per cent operative mortality was reported. This includes patients over the age of 50, in whom the mortality rate is four times higher than in those under 50. Recent series report even lower mortality rates, comparable at least to those following jejunoileal bypass (Alden, 1977; Buckwalter, 1977; Griffen, 1977; Gomez, 1979).

Despite the theoretical risk of producing a situation conducive to stomal ulceration, a stomal ulcer rate of only 1·8 per cent has been reported (Mason et al., 1978). No metabolic or nutritional deficiencies have been documented either in other series or in our group of 12 patients. Particularly gratifying has been the stable gastrointestinal function with no late vomiting or dumping and normal stool frequency and consistency. Thus, there is increasingly good evidence that surgical intervention in carefully selected patients is justifiable and, in most patients, beneficial. Longer follow-up studies are required to determine that the weight remains stable and that there are no late complications.

Hepatic resection for trauma, tumour and biliary obstruction

L. H. BLUMGART, J. K. DRURY AND C. B. WOOD*

SUMMARY

Hepatic resection was performed in 37 patients. Fifteen emergency procedures were undertaken for blunt trauma and 16 patients had elective resection for hepatic tumour. A further 6 resections were performed for benign biliary tract obstruction. The importance of preoperative assessment and the indications for resection are discussed particularly in relation to resection for biliary obstruction. Operative procedures are outlined and the technique of extended left lobectomy is described in detail.

THE detailed anatomical studies of McIndoe and Counsellor (1927), Healey (1954), Goldsmith and Woodburne (1957) and others formed the basis for technical developments in liver surgery and have resulted in the precise documentation of the formal operations involving partial hepatectomy. Liver resection has thus become more widely used in the treatment of hepatic disorders, although the indications for partial hepatectomy in certain conditions are still a matter for debate. The place of hepatic resection in injury has become more clearly defined (Walt, 1978), but its value in tumours of the liver and bile ducts is still being determined. Resection is used only infrequently in benign biliary obstruction.

This paper reports a consecutive series of patients submitted to hepatic resection. The indications for surgery and management of patients requiring resection for blunt liver trauma, tumour and biliary obstruction are discussed.

Preoperative considerations

Diagnosis and assessment

Trauma: In patients who have sustained blunt abdominal trauma, awareness of possible liver damage and astute clinical judgement are important. Classic signs of intra-abdominal injury may be present, but in some cases of extensive liver injury shock is often not a presenting feature and there may be minimal physical signs (Walt, 1969; Vajrabukka et al., 1975). The presence of fractured ribs and, in addition, fractures of the right upper limb is common (Vajrabukka et al., 1975). In this series abdominal paracentesis was not employed and peritoneal lavage only rarely. Emphasis was placed on careful observation and repeated examination, laparotomy being performed on suspicion (Bolton et al., 1973).

Special methods of investigation including ultrasound, isotope scanning and selective coeliac axis angiography were only used in patients presenting in a less acute manner. In all patients a baseline coagulation screen was obtained, if possible before transfusion was commenced (Vajrabukka et al., 1975).

Tumour and biliary tract obstruction: In the selection of patients for elective liver resection for tumour or biliary tract obstruction extensive investigations are essential for accurate preoperative assessment.

In patients presenting with biliary tract obstruction, whether benign or malignant, a combination of grey scale ultrasound, fine needle percutaneous transhepatic cholangiography (PTC) (*Fig.* 1) and endoscopic retrograde choledochopancreatography (ERCP) was used in an ordered manner (Benjamin et al., 1978; Blumgart, 1978) to define precisely the anatomical location, extent and nature of the obstruction present.

Diagnosis of liver tumour was based on the history, physical examination, serological tests, isotope and ultrasound scanning and selective hepatic arteriography. A target liver biopsy was obtained using a Tru-cut needle under direct laparoscopic control. This technique provided visualization of the extent of tumour spread and gave an assessment of operability. Patients with hepatic and bile duct tumours were screened for extrahepatic deposits, using a combination of chest X-ray, skeletal survey and/or isotopic bone scan. Patients with secondary tumours in the liver arising from colonic primary sites also underwent barium enema or colonoscopic examination.

Selective arteriography and splenoportography were reserved for patients in whom it was considered that resection might be feasible. These two investigations demonstrated not only the presence of tumour but, importantly, the anatomy to be encountered at operation (*Fig.* 2). In particular, assessment of the involvement of vessels at the porta hepatis is essential in planning operative approaches. Inferior venacavography and hepatic venography were also performed to assess the extent of tumour involvement in these structures.

Tumours were considered irresectable in the presence of multiple deposits in both lobes of the liver and in patients with involvement of extrahepatic structures or radiological evidence of invasion (*Fig.* 3), but not compression (*Fig.* 4) of the inferior vena cava. Likewise, occlusion of both (but not one) branches of the portal vein was taken as an index of inoperability.

The general condition of the patients was assessed carefully and special attention was paid to the pathophysiological effects of jaundice (Blumgart, 1978), to the presence or absence of coagulation defects and to the assessment of renal function (Dawson, 1965; Allison et al., 1978).

Prophylactic antibiotics were used in patients with biliary tract obstruction because an increased incidence of biliary infection is known to occur in these cases (Flemma et al., 1967; Keighley, 1977; Shingleton, 1977).

Operative techniques

The incision used depended upon circumstances. Exploration for liver injury was initially performed through a right upper paramedian rectus-splitting incision or a midline incision. This was extended as a thoracoabdominal incision, either through the seventh interspace with incision of the diaphragm towards the vena cava, or more recently by means of a median sternotomy (Miller, 1972). This latter approach is rapid, spares disruption of either pleural cavity and gives good access to the major hepatic veins and the intracardiac inferior vena cava. Should the diaphragm require to be split, this can be done through the central tendon. Laparotomy for tumour was through either a bilateral oblique 'roof-top' incision or a thoracoabdominal incision similar to that used in cases of trauma.

Formal hepatic lobectomy either in the emergency or elective situation was preceded by isolation of the vascular and biliary structures of the porta hepatis. The vessels and ducts supplying the segment to be excised were then ligated and divided. For tumours involving the porta hepatis we have employed a 'liver-split' technique (Templeton and Dodd, 1963; Waddell, 1967). The liver substance is divided in the plane just to the left of the gallbladder fissure using a finger fracture technique and deepening the incision of the liver substance posteriorly in a slightly oblique direction towards the vena cava. This initial hepatotomy (*Fig.* 5) allows intrahepatic evaluation without committing the surgeon to resection. Final assessment of operability is made and if it is decided to proceed

with lobectomy then the appropriate vessels can be divided (*vide infra*).

Liver tissue was sectioned using a combination of incision, diathermy and the finger fracture dissection technique (Foster and Berman, 1977). The hepatic veins were frequently approached from within the liver substance, especially in resection for trauma (Blumgart and Vajrabukka, 1972). In patients with large tumours extending close to the vena cava, formal dissection of the hepatic veins was carefully carried out from below upwards, thus allowing the liver substance to be lifted free from the vena cava. Large quantities of liver parenchyma were never compressed but it was found that absorbable liver buffers (Wood, Capperauld et al., 1976) allowed gentle compression of liver tissue with efficient haemostasis.

Choledochotomy and T tube drainage was used in all but 3 patients undergoing right hepatic lobectomy or extended right hepatic lobectomy for trauma but not in resection carried out for tumour. In patients with biliary tract obstruction requiring removal of a portion of the biliary ductal apparatus reconstruction was always over a transhepatic or transjejunal tube in order to splint the anastomosis (Benjamin and Blumgart, 1979). Postoperative drainage was used in all patients.

Hepatic resection

Right hepatic lobectomy and extended right hepatic lobectomy (trisegmentectomy) were performed by standard methods (Balasegaram, 1970; Longmire et al., 1974; Ong and Lee, 1975; Starzl et al., 1975; Adson and Beart, 1977; Ong, 1977). In one patient submitted to trisegmentectomy for primary hepatoma, invasion and complete occlusion of the right branch of the portal vein was demonstrated by splenoportography. Adequate exposure at the porta hepatis allowed excision of a segment of portal vein at its bifurcation with direct suture repair (*Fig*. 2).

Left lobectomy was likewise performed by standard methods and left lateral segmentectomy using the clamp described by Storm and Longmire (1971). Liver buffers (Wood, Capperauld et al., 1976) were placed before the clamp was released in order to control haemorrhage.

Extended left hepatectomy: In 2 patients resection of liver tissue involved removal of the entire left lobe of the liver, the quadrate and caudate lobes and a portion of the right lobe. We refer to this procedure as extended left hepatectomy. In both instances the operation was necessitated by tumour involving the hilar structures, mainly on the left side.

The approach varies subtly from that adopted in carrying out the formal operations of right or left hepatectomy in which the aim is to devascularize that portion of the liver to be removed. In patients with tumour involving the hilus, the important objective of maintaining a vascular supply, venous effluent and biliary drainage to the remaining non-diseased segment must be specially borne in mind throughout the dissection. The structures feeding the porta hepatis should initially be isolated so that control can readily be obtained when necessary. The liver is then split, as described above, just to the left of the gallbladder fossa, deepening the incision posteriorly to skirt the right margin of the tumour with adequate clearance. As this incision is deepened it becomes easier to assess resectability. In both patients in whom this approach was employed the course of the right branch of the portal vein and associated arterial and biliary structures was clearly seen and the antero-inferior and posterior segmental branches of the portal triad were preserved. During the dissection the middle hepatic vein and left hepatic vein were either ligated separately or, if the middle hepatic vein drained into the left, this was dealt with alone. The right hepatic vein lies further back between anterior and posterior segments of the right lobe of the liver and should have been demonstrated preoperatively by hepatic venography to be clear of tumour.

In the 2 patients in whom this approach was used, selective arteriography and splenoportography had revealed the arterial supply to the right lobe of the liver to be free from tumour involvement but the left branch of the portal vein was occluded in each instance (*Fig*. 6). In both cases there proved to be involvement of the bile duct at the confluence by tumour invasion.

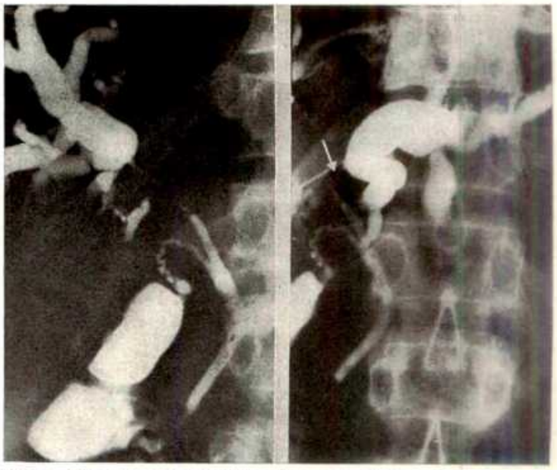

Fig. 1. Percutaneous transhepatic cholangiograms demonstrating both the right and the left (arrowed) intrahepatic ductal system of the liver in a 50-year-old man with a 1-month history of painless obstructive jaundice. The cholangiogram performed via the right lobe of the liver shows obstruction of the right hepatic duct by a carcinoma which extends to the common hepatic duct. The PTC performed via the left lobe shows obstruction to the main left hepatic duct (arrowed) but, in addition, there is an accessory duct opening into the common hepatic duct. The main left hepatic ductal system is grossly dilated.

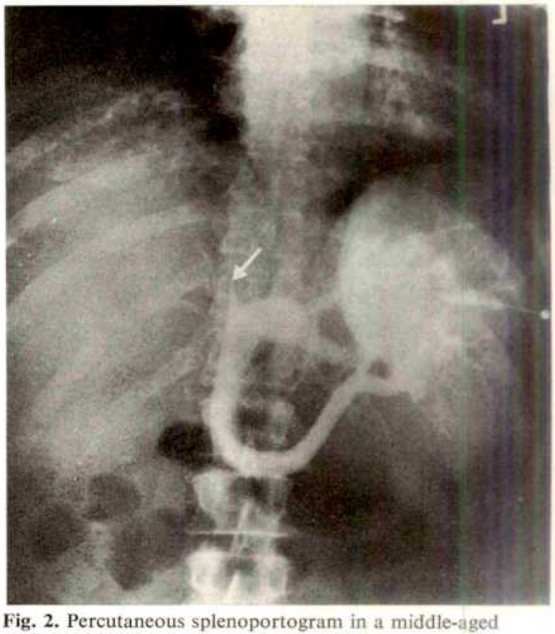

Fig. 2. Percutaneous splenoportogram in a middle-aged patient with a large primary hepatocellular carcinoma occupying the entire right lobe of the liver. Note displacement of the main trunk of the portal vein with occlusion of its right main branch (arrowed). The left branch of the portal vein is intact. Knowledge of such portal venous involvement is vital during operation, particularly during dissection at the hilus of the liver.

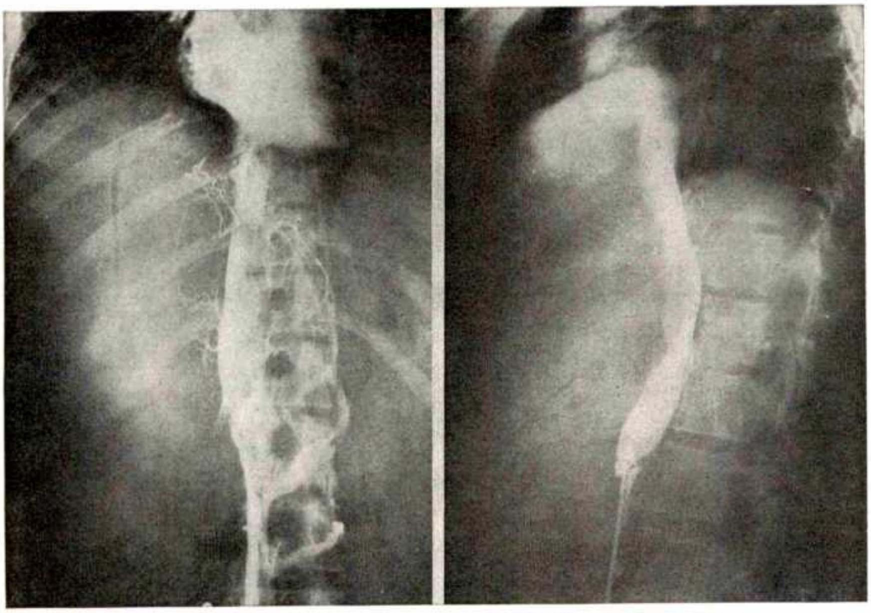

Fig. 3. Inferior venacavography, both in the anteroposterior and lateral views, in a 19-year-old patient with a primary hepatocellular carcinoma. There is invasion of the inferior vena cava seen as filling defects in both projections and collateral circulation reflecting partial obstruction. This must be differentiated from the appearances shown in *Fig*. 4.

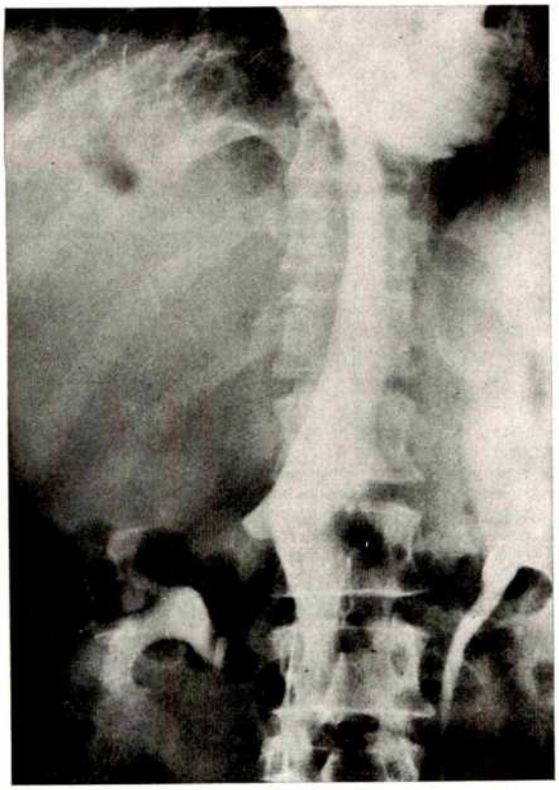

Fig. 4. Inferior venacavogram in a 54-year-old man with primary hepatocellular carcinoma involving the right lobe of the liver. There is compression but not invasion of the inferior vena cava. (Same case as in *Fig*. 2.)

J. B., a 51-year-old male, presented with painless obstructive jaundice. PTC and ERCP demonstrated a complete block at the common hepatic duct bifurcation. Aspiration of bile at ERCP established the diagnosis of malignancy. Selective hepatic arteriography was normal but splenoportography revealed that the left branch of the portal vein was almost totally occluded (*Fig*. 6).

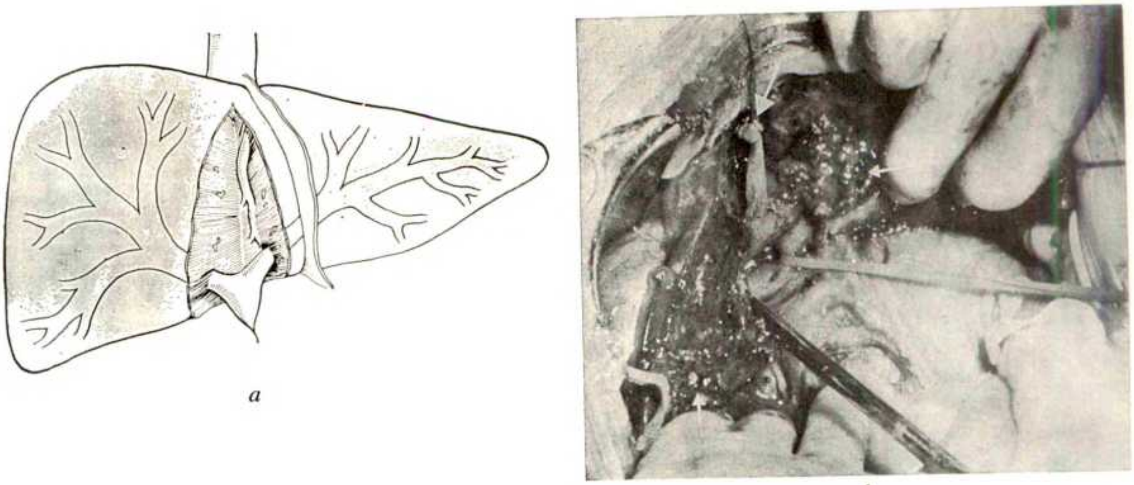
The feasibility of liver resection could not be assessed until hepatotomy was performed. The liver was finger fractured in the vascular plane and branches of the middle hepatic vein ligated. The confluence of the bile ducts was displayed showing considerable extension of tumour to the left and posteriorly as well as into the right lobe for a short distance. The supraduodenal common bile duct was transected and turned upwards (*Fig*. 5). The portal vein was isolated below its bifurcation and its right branch was dissected upwards into the liver.

The left portal vein was transected at its origin and the defect closed by direct suture. The tumour was traced into the right lobe of the liver and clearance obtained, the right intrahepatic ducts being sectioned and three separate branches identified to be clear of tumour. The left lobe of the liver was mobilized and the left hepatic vein divided. The caudate lobe was mobilized from the vena cava by serial dissection of the minor hepatic veins from below upwards and the entire left lobe, caudate lobe, quadrate lobe and a segment of the right lobe removed *en masse*.

A Roux-en-Y loop of jejunum was fashioned and three separate hepaticojejunostomy anastomoses made, each being splinted (two by means of transhepatic tubes and one via a transjejunal tube).

Histology of the specimen confirmed the presence of a cholangiocarcinoma extending well into the caudate lobe and left lobe of the liver. The excision edge was clear of tumour.

A. J., a 16-year-old female, presented with a 2-week history of right upper quadrant pain, jaundice and one episode of haematemesis. There was a previous history of oral contraceptive ingestion. Alphafetoprotein estimation was negative. PTC showed gross dilatation of the right intrahepatic bile ducts and the common bile duct. The left hepatic duct was not outlined. Laparotomy revealed a mass in the porta hepatis



a

b

Fig. 5. *a*, The performance of a 'liver split' procedure in a patient with benign bile duct stricture. Note that the incision in the liver substance is made several centimetres to the right of the ligamentum teres and just to the left of the gallbladder fossa (gallbladder removed in this instance). The incision in the liver substance is just to the right of the middle hepatic vein which is shown in the depth of the hepatotomy. *b*, The operative field in a 51-year-old man with carcinoma involving the confluence of the bile ducts and extending well into the left branch of the portal vein (*see Fig*. 6). A 'liver split' has been performed and the right and left lobes of the liver are seen separated by the operator's fingers (small arrows). The common bile duct has been transected above the duodenum and turned upwards into the liver split (large arrow). The portal vein is clearly seen in the depth of the hepatotomy and its left branch has a sling at the orifice, the vein clearly being implicated by the tumour in the left hepatic duct. The hepatic artery has been dissected and is evident below the portal vein.

involving mainly the left side but extending also into the right and caudate lobes. Choledochotomy was performed and loose tumour removed which proved to be hepatocellular carcinoma. A tube was left in the common hepatic duct and the abdomen was closed. The patient was then referred to Glasgow Royal Infirmary. Selective hepatic arteriography revealed the left hepatic artery arising from the left gastric artery and supplying a large tumour mass in the area of the porta hepatis. The right hepatic artery arose from the superior mesenteric artery and appeared to be clear of the tumour and not involved in its blood supply. Splenoportography showed complete occlusion of the left branch of the portal vein. At subsequent exploration the enlarged common bile duct was completely transected and loose tumour withdrawn. The tumour did not invade the wall of the main duct but the orifice of the left hepatic duct was completely occluded. The upper portion of the common hepatic duct was turned upwards and a segment of its wall excised at the junction of the left hepatic duct, the defect created being closed by direct suture.

The liver was then split to the left of the gallbladder fossa, the incision being deepened so as to skirt the right margin of the tumour. Dissection of the portal vein, removal of the orifice of the left portal vein and subsequent repair of the defect was similar to that in the previous case. The left hepatic artery was ligated and the left lobe of the liver mobilized. The caudate lobe was dissected free from the inferior vena cava and the operation completed by division of the left hepatic vein. Continuity of the common bile duct was restored by end-to-end anastomosis, and splinted by a transhepatic tube passed through the right lobe of the liver.

Both these patients made an excellent recovery from operation.

Results

A total of 37 hepatic resections has been carried out (*Table I*). The age range of the patients was from 9 to 59 years. There was 1 immediate postoperative death (defined as death during or within 24 h of operation) and 4 further patients died before leaving hospital.

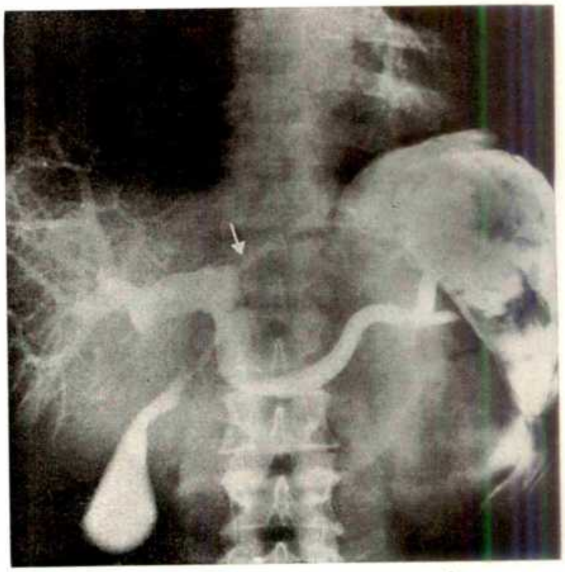


Fig. 6. Splenoportography showing almost complete occlusion of the left branch of the portal vein (arrowed). This patient (same case as in *Fig*. 5) presented with a 2-week history of painless obstructive jaundice and was found on PTC and ERCP to have a cholangiocarcinoma at the confluence of the bile ducts involving the main trunk of the right hepatic duct and extending well into the left lobe of the liver. The X-ray shows the right branch of the portal vein free of tumour and similarly selective hepatic arteriography had shown the right hepatic artery to be clear of tumour. There is contrast medium in the gallbladder from ERCP carried out a day earlier.

Table I: PATIENTS AND SURVIVAL FOLLOWING HEPATIC RESECTION

Group	No. of patients	Hospital mortality	Overall survival	Survival period before death	Follow-up period of survivors
Trauma	15	3 (20%)	12 (80%)	10 h–10 d	12 mth–12 yr
Tumour	16	2 (12·5%)	6 (37·5%)	8 d–4½ yr	5 mth–6 yr
Primary	7	1 (14·2%)	4 (57%)	12 d–2 yr	5 mth–2 yr
Secondary	9	1 (11%)	2 (22%)	5 mth–4½ yr	26 mth–7 yr
Biliary obstruction	6	0	6 (100%)	—	11 mth–5½ yr

Eight other patients have died of cancer during follow-up at periods varying from 5 months to 4½ years. All the patients surviving liver resection for liver injury or for benign biliary obstruction remain alive and well.

Trauma

Fifteen patients (age range 9–39 years) were submitted to emergency resection for hepatic trauma. Twelve patients underwent right lobectomy while 2 had extensive resectional débridement and suture and 1 had left lateral segmentectomy. Three patients died, 2 of associated head and chest injuries and 1 with associated injuries and concomitant post-traumatic pancreatitis and renal failure. In each instance hepatic resection controlled haemorrhage and biliary leakage.

The first 8 patients have been described in detail (Vajrabukka et al., 1975). All 7 patients treated since then have survived and all 12 survivors are alive and well at periods ranging from 6 months to 13 years after operation.

Tumour

Sixteen patients (age range 16–59 years) underwent hepatic resection for tumour. Seven patients had primary tumour of the liver or biliary system; trisegmentectomy was performed in 4 patients and extended left hepatic lobectomy in 2 patients with primary hepatocellular carcinoma, cholangiocarcinoma or gallbladder carcinoma. In 1 patient a left lateral segmentectomy was performed for an intrahepatic haemangioma. In 3 patients tumour involvement of the portal vein was noted.

Nine patients had resection of secondary hepatic deposits, the primary tumour sites being colon or rectum in 6, small intestinal carcinoid in 2 and hypernephroma in 1 patient. One right hepatic lobectomy, 3 trisegmentectomies, 2 lateral segmentectomies and 3 wedge excisions were performed in these patients.

Six patients (37·5 per cent) are alive, one of whom has recurrent cholangiocarcinoma, the period of follow-up being from 5 months to 7 years. Two patients with primary liver tumours died 18 months and 2 years respectively after resection. Of the 9 patients with secondary tumours, 6 died between 5 months and 4½ years after surgery.

Two patients died in the postoperative period (12·5 per cent). Both patients died from haemorrhage. The first patient, a 38-year-old woman, had a left hemicolectomy for splenic flexure carcinoma and was noted to have a 2-cm metastatic deposit in the right lobe of the liver. Eighteen months later, when she was referred for hepatic resection, the solitary nodule was 8 cm in diameter and close to the hilus. Tumour was found to be involving the right branch of the portal vein and the origin of the left branch. Trisegmentectomy was performed, during which procedure the portal supply to the left lobe was compromised and the patient died 8 days later from haemorrhage caused by an irreversible coagulation defect. On the basis of this experience we now perform splenoportography in all patients with potentially resectable tumours close to the hilus of the liver.

A further patient died with uncontrollable haemorrhage from gastric erosions 12 days postoperatively. It is now our policy to give prophylactic cimetidine to all jaundiced patients undergoing resection.

In addition to the possible curative role of hepatic surgery for tumour, several patients have had complete relief of symptoms following palliative resection of the primary or secondary hepatic lesion. One patient suffering considerable right hypochondrial pain and jaundice was afforded excellent symptomatic relief for 15 months before developing bone metastases.

Benign biliary obstruction

Six patients (age range 26–58 years) have been submitted to hepatic resection for benign bile duct stricture. There was no hospital mortality and all patients are alive and well at periods ranging from 11 months to 5½ years.

The operations carried out were left lobectomy with intrahepatic hepaticojejunostomy for 1 patient with a high bile duct stricture following liver injury for which right hepatic lobectomy had previously been performed; right hepatic lobectomy with intrahepaticojejunostomy in 1 patient with iatrogenic high bile duct stricture and quadrate lobectomy was performed in 4 patients for iatrogenic bile duct stricture.

Postoperative progress

All cases involving major hepatic resection were nursed initially in an intensive care unit, the patients spending 24 h on intermittent positive pressure ventilation as a routine. The main immediate dangers occurring after hepatic resection are, first, coagulation defects due to large volumes of transfused blood and diminished production of hepatic clotting factors and, secondly, hypoglycaemia following depletion of glycogen stores.

Impairments of blood clotting were reversed with the use of fresh frozen plasma, fresh blood and platelet transfusion. An irreversible coagulation defect occurred only in the patient with liver failure consequent on hepatic necrosis of the remaining liver segment. Blood sugar was monitored regularly, particularly during the first 48 h postoperatively and only 1 patient required 50 per cent dextrose infusions.

The only other major postoperative complication was subphrenic abscess which developed in 3 patients and in 1 this was complicated by penetration of the diaphragm by the abscess with the development of a right-sided empyema.

Wound infection necessitating drainage of the wound developed in 3 further patients.

Following hepatic resection there was a transient rise in ALT and alkaline phosphatase levels and all the patients were jaundiced to a variable degree. The total serum protein levels fell, this being mainly due to a fall in the albumin fraction, reaching a nadir of 2·3–2·5 g/l at about 2 weeks after surgery. In some patients albumin supplementation to a total of 100 g/day was given but this did not appear to affect the speed at which the proteins returned to normal, this usually occurring by the sixth to seventh postoperative week.

Discussion

Hepatic resection is a major operation and the indications for its use require careful assessment. The mortality and morbidity are considerable and resectional methods should not be employed where more simple methods will suffice. On the other hand, it is important to realize that in some situations less radical approaches have no chance of success.

The indications for resection are becoming more clearly defined, although fine judgement is required at the time of operation. Major shattering wounds of the liver cannot be sutured and while temporary packing may be of value and allow transport of the patient to a centre where resection can be performed (Calne et al., 1979; Walt, 1978), it is generally contraindicated and is associated with a high incidence of secondary haemorrhage, infection and biliary leakage.

Dramatic arrest of bleeding can follow arterial ligation and in some circumstances this may be safely carried out (Aaron et al., 1975). The portal circulation is adequate to provide liver nourishment and the liver deprived of its arterial supply readily develops a collateral circulation. However, vascular ligation to a segment of the liver may not control haemorrhage and should be used judiciously, particularly in the presence of extensive bruising in the porta hepatis. Furthermore, more recent evidence has shown a considerable mortality (31 per cent) for patients treated by vascular ligation (Flint et al., 1977) and the procedure may be followed by severe deleterious effects, particularly in the presence of concomitant infection. Ligation should not be used in the presence of shattered liver tissue requiring resectional débridement or lobectomy. Immediate control of haemorrhage should not necessarily be bought at the expense of later sepsis and delayed mortality (Atik, 1976).

Wounds accompanied by much devitalization of liver tissue warrant resectional methods in their treatment (Blumgart and Vajrabukka, 1972; Blumgart, 1978). Resectional débridement may be safely employed to remove large amounts of devitalized liver tissue since it exposes the underlying blood and biliary vessels which may be controlled by direct suture ligation. However, for wounds which shatter and disrupt the liver substance deep within its pulp and in which débridement along non-anatomical lines at the periphery of a liver lobe is not possible, formal liver resection is indicated. The need for such resection is almost confined to severe blunt injuries and shotgun wounds and all the cases described in this paper followed severe disruptive blunt injury to the right lobe of the liver.

Mortality and morbidity for blunt liver injury have decreased markedly and the improvement has been in part attributable to more liberal use of resection when necessary. On the other hand, a recent American survey (Walt, 1978) of patients with injury severe enough to warrant resection estimated the mortality of resection to be approximately 50 per cent and argued for a limited use of extensive resection in the emergency situation. Such arguments are valid but should be tempered by the realization that it is difficult to determine the true mortality of liver injury alone. Factors such as speed of transfer to hospital, the number of other organs injured and the experience of the surgical team should be taken into account and mortality figures of 30 per cent or less are now regularly recorded (Little and Williams, 1969; Walt, 1969; Blumgart and Vajrabukka, 1972). In our experience, 3 out of 15 patients (20 per cent) have died following resection for major blunt injury.

The management of hepatic tumours is depressing since untreated patients with hepatocellular carcinoma survive only 3–6 months after diagnosis. Patients with secondary deposits from a primary site in the gastrointestinal tract cannot expect to live 5 years, and the majority will be dead within a year (Foster, 1970; Wood, Gillis et al., 1976; Foster and Berman, 1977; Terblanche, 1977). The results of palliation using radiotherapy and chemotherapy are disappointing. There is some recent evidence that doxorubisin may be helpful in primary hepatobiliary cancer (Johnson et al., 1978), but other studies which have examined these measures together with hepatic dearterialization have suggested that they yield no better results than simple symptomatic relief (Ong and Chan, 1976). Hepatic transplantation for tumour has also been disappointing, and although occasional long term survivors are reported (Calne and Williams, 1977; Putnam and Starzl, 1977) hepatic resection still represents the greatest prospect of cure (Shiu and Fortner, 1975; Ong and Chan, 1976).

Our experience of hepatic resection for primary hepatoma and cholangiocarcinoma is small but nevertheless some important points are worthy of comment. First, of eight primary hepatocellular carcinomas seen in a 5-year period, 3 were in cirrhotic livers and were inoperable. However, 2 of the remaining 5 cases were suitable for resection. Although 1 patient died 18 months after surgery as a result of the development of bone metastases and the other, a girl aged 16, died with recurrent tumour 23 months after initial surgery, excellent palliation was obtained. In both these patients there was involvement of the portal vein and yet resection proved possible by extending the dissection along the course of the right branch of the portal vein within the liver substance while preserving the posterosuperior and anteroinferior branches of vessels and ducts. This allows an extension of the limits of operability for tumour close to the hilus of the liver. There is no indication for resection if there is evidence of extrahepatic involvement or if there are several malignant foci in the liver. On the other hand, hilar involvement with spread of the tumour across anatomical boundaries is no bar to resection. McBride and Wallace (1972) and Miller (1974) have described multiple segmental resections of the liver for hepatic growths and although Starzl et al. (1975) doubt whether there is a necessity for such an operation, we believe, as do Ong and Chan (1976), that such dissection is occasionally necessary and can give good results.

The risk of operation and chance of success must be weighed against the expectations of complete hepatic resection and liver transplantation. However, transplantation is hazardous and the patient requires postoperative immunosuppression.

The timing of resection for secondary tumour is important, and because of the risks of infection, it should only rarely be performed at the same time as colonic resection. On the other hand, we believe that there is no reason to wait for prolonged periods before proceeding to hepatic resection, nor do we believe that there is any particular advantage in selecting for resection only those cases who develop secondary growths some years after removal of the primary. In experienced hands the mortality of resection for metastatic lesions is small (Ong and Lee, 1975) and a 5-year survival of between 15 and 40 per cent is to be expected (Wilson and Adson, 1976; Foster and Berman, 1977).

The relief of biliary obstruction by means of hepatic resection has not been widely practised but there are two main indications. First, hepatic resection can be valuable in patients with primary tumours at the confluence of the bile ducts. Inoperable cholangiocarcinoma in this area can be managed by means of intubation as described by Terblanche and Louw (1973). However, for potentially resectable lesions a more aggressive surgical approach seems warranted. Precise preoperative evaluation, including PTC, ERCP, arteriography and splenoportography, will define most clearly inoperable lesions and leave a few selected cases for attempted resection. The technique we describe in which an initial hepatotomy is carried out and the tumour assessed either for local excision or for excision together with hepatic lobectomy has allowed us to proceed to a resection so extensive as to necessitate three separate hepaticojejunostomy anastomoses to a single loop of jejunum within second order ducts in the right lobe of the liver (Blumgart, 1978). Such initial hepatotomy does not preclude palliative intubation should the lesion prove inoperable.

Secondly, hepatic resection can be employed in certain patients with benign biliary strictures. It is true that the majority of iatrogenic bile duct injuries can be dealt with by an infrahepatic reconstruction or by use of the 'mucosal graft' technique (Smith, 1972). The long term results of the latter procedure remain to be fully assessed and the method is inapplicable in the presence of small intrahepatic ducts. We have preferred splitting the liver by means of hepatotomy in a similar manner to that described above (Benjamin and Blumgart, 1978), so allowing mucosa-to-mucosa suture. In 2 of our cases hepatic resection was performed to allow access for the construction of an intrahepaticojejunostomy. Modest resection of the quadrate lobe of the liver overlying the hepatic hilus has also been performed in a number of cases and has allowed precise mucosa-to-mucosa suture. All the 6 patients in whom we carried out resection and anastomosis for benign bile duct stricture are alive and well at periods varying from 9 months to 5 years. In addition, 3 other patients not included in the series had hepatotomy (liver split) without hepatic resections. Of these, 2 are alive and well 18 months and 1 month respectively after operation, the other died in the postoperative period with bacteraemia and multiple organ failure.

Hepatic resection is well tolerated and regeneration of the liver is rapid (Blumgart et al., 1971). When performed for severe injury to the liver the procedure is life-saving and the long-term results excellent. Similarly, resection of the liver substance to allow access for reconstruction by means of biliary enteric anastomosis in selected cases gives good results. Hepatic resection for tumour offers, at best, the prospect of cure and at the very least significant prolongation of life with excellent palliation in a significant number of patients. The operative and intra-hospital mortality is acceptable.

In vitro dissolution of human gallstones: the efficacy of heparinized solutions

J. TOOULI, B. W. A. WILLIAMSON, H. GOOSZEN AND L. H. BLUMGART*

SUMMARY

The use of heparinized solutions to dissolve or fragment stones retained in the biliary tree after surgery is still controversial. In this in vitro study heparin in concentrations of up to 100 000 u/l did not dissolve or fragment the stones examined, nor did it enhance the dissolution properties of the bile salt, sodium cholate.

THE treatment of stones retained in the biliary tree following surgery with solutions introduced via the T tube is well established. Different claims of success have been made for a variety of solutions, the most consistently effective in dissolving gallstones being bile salt solutions (Toouli et al., 1975).

The role of heparin in the treatment of stones retained in the biliary tree is controversial. Clinical studies have shown a high rate of success in eliminating stones from the biliary tree (Gardner, 1973). However, *in vitro* studies have cast doubt on the claims that heparin acts by dissolving or fragmenting the gallstones (Hardie et al., 1977).

In this report we describe the findings of an *in vitro* study of the effect of heparin in dissolving cholesterol gallstones. In addition, the combined effect of sodium cholate and heparin solutions was compared with that of sodium cholate solutions alone.

Materials and methods

Gallstones

Human cholesterol gallstones were obtained from the gallbladder of one patient having cholecystectomy. The stones were rinsed with normal saline and six representative stones were analysed for their cholesterol content. These stones were composed of 95 ± 5 per cent cholesterol. The stones were multifaceted and of variable size and weight. Stone weight was used as the parameter that determined changes in the stone brought about by immersion in the test solutions.

Solutions

The composition of the various solutions tested is shown in *Table I*. The solutions were prepared as follows:

1. Sodium cholate (200 mM) (Weddel Pharmaceuticals). The bile salt was dissolved in sodium chloride (150 mM).
2. Heparin (Weddel Pharmaceuticals). Sodium heparin was added to sodium chloride (150 mM) at a concentration of 100 000 u/l. The heparin contained 0·15 per cent chlorocresol as a preservative.
3. Sodium cholate (200 mM) plus heparin. Sodium heparin was added to sodium cholate (200 mM) solutions at concentrations of 25 000, 50 000 and 100 000 u/l of solution.

Table I: TEST SOLUTIONS

Sodium chloride 150 mM
Sodium cholate 200 mM
Sodium cholate 200 mM plus heparin 25×10^3 u/l
Sodium cholate 200 mM plus heparin 50×10^3 u/l
Sodium cholate 200 mM plus heparin 100×10^3 u/l
Sodium chloride 150 mM plus heparin 100×10^3 u/l

Dissolution experiments

Twenty millilitres of each solution were placed in 50-ml flasks and a single human cholesterol gallstone of known weight was placed in each flask. The flasks were placed in a constant temperature water bath at 37 ± 1 °C and gently agitated.

On days 4, 8, 12 and 16 the stones were removed from the flasks, rinsed with sodium chloride and left to dry at room temperature for an hour on filter paper. The solutions were renewed, the stones weighed and then replaced in the flasks. To overcome the possibility of bacterial degradation of the heparin solutions, sodium heparin was added to the flasks on days 2, 6, 10 and 14 in quantities identical to the initial concentrations. Therefore, between these days and the days when the solutions were renewed, the total concentration of heparin in each flask was doubled.

Estimation of rate of dissolution

Four stones were used in each group. The stones were selected so that the weight range in each group was similar. In order to facilitate comparison, the stone weights on each test day were expressed as a percentage of the original weight. The means of the percentage changes in weight for each test day were determined.

Using Student's *t* test, the results were compared for each solution tested. The statistical analysis was carried out on the weights of the individual stones on the test days and the means of the percentage changes in weight.

Results (Table II)

Effect of normal saline

Four stones were immersed in normal saline solution for 16 days. There was no significant change in the weight of the stones.

Effect of addition of heparin

Four stones were immersed in heparinized saline solution (concentration = 100 000 u/l). There was no significant change in the weight of the stones during 16 days of continuous immersion. In addition, there was no visible fragmentation of the stones.

Effect of sodium cholate solution

Four stones were immersed in 200 mM sodium cholate solution. There was a significant ($P < 0{\cdot}05$) decrease in the weight of all the stones, indicating dissolution. The stones were reduced to less than 50 per cent of their initial weight after 16 days of continuous immersion.

Effect of addition of heparin

Heparin was added to 200 mM sodium cholate solutions to form three groups of solutions at concentrations of 25 000 u/l, 50 000 u/l and 100 000 u/l respectively. In each group of solutions there were four flasks and a stone was added to each flask. There was a significant ($P < 0{\cdot}05$) decrease in the weight of all the stones, and this decrease in weight was progressive over 16 days. There was no significant difference in the weight loss achieved by the solutions containing different concentrations of heparin, and there was no significant difference in the weight loss achieved by solutions of sodium cholate alone and sodium cholate plus heparin. Therefore, heparin did not enhance the dissolving capacity of sodium cholate

solutions. In addition, there was no evidence of fragmentation in any of the stones.

Discussion

The aim of this study was to investigate under controlled laboratory conditions the claims that heparin is effective in dissolving human cholesterol gallstones.

Our results show that heparin alone does not cause dissolution or fragmentation of human cholesterol gallstones. In addition, they show that heparin does not accelerate or enhance the dissolving capacity of sodium cholate (200 mM) solutions at the concentrations tested.

There is still much dispute as to the effectiveness of heparin in dissolving cholesterol gallstones. Gardner (1973) has reported success in treating, with heparin, stones retained in the common bile duct, and Lahana et al. (1974) have shown fragmentation of stones suspended in heparinized solutions *in vitro*. However, Hardie et al. (1977) and McCombs et al. (1973) have reported no effect of this substance on gallstone fragmentation or dissolution. The present study supports the findings of the latter authors. One of the reasons for the discrepancies in the results from different centres may be variation in methodology. In some studies the stones were allowed to float freely (Toouli et al., 1975), in others they were retained in a basket or bag (Hardie et al., 1977) and in others the solution was actively stirred mechanically (Lahana et al., 1974). Methods that actively disturb the suspending solution may traumatize the stones and therefore promote fragmentation.

We have overcome these problems in the present study by simplifying the design. The stones were immersed free in solution without the added mechanical trauma of a stirrer within the flasks. Potential criticisms of saturation or degradation of the dissolution agent were overcome by renewing the solutions every 4 days and by the addition of extra heparin after alternate 48-h periods. The action of heparin in producing fragmentation of gallstones is controversial. Ostrewitz and Gardner (1970) have proposed a theoretical argument for the action of heparin, based on adsorption of the highly charged heparin polymer to the outer surface of small stone fragments with consequent repulsion of adjacent particles due to their similar negative charge. While this explains the action of heparin in stabilizing small particles in colloidal solutions, it does little to explain the fragmentation of individual large gallstones, which has been reported by these workers.

Furnival et al. (1977) observed an increased rate of gallstone dissolution and fragmentation when heparin was added to sodium cholate solutions. This has not been confirmed in the present study. The theoretical mechanism proposed by these workers, involving increased repulsion of bile salt micelles, assumes that the highly negatively charged heparin polymer can be incorporated into the negatively charged micelles. That adsorption of two aggregates of similar charge is possible under these circumstances has not been proved. The assumption that increased separation of bile salt micelles is associated with increased cholesterol solubilization is also unproved.

On the basis of the present study, the use of heparin alone, or to augment the available bile salt preparations, in dissolving stones retained in the biliary tree cannot be recommended.

Intestinal bacterial metabolism of protein and bile acids: role in pathogenesis of hepatic disease after jejuno-ileal bypass surgery

P. R. POWELL-JACKSON, D. P. MAUDGAL, DOROTHY SHARP, ALISON GOLDIE AND J. D. MAXWELL*

SUMMARY

Jejunal bacterial colonization and intestinal metabolism of bile acids and protein by bacteria have been investigated in 12 patients with abnormal liver histology following jeujno-ileal bypass surgery for obesity.

Aerobic and/or anaerobic colonic flora was present in jejunal aspirates from 8 of 12 bypass patients, but in none of the controls. Intestinal protein metabolism and bile acid deconjugation (measured by urinary indican excretion and ^{14}C-glycocholic acid breath test) was significantly enhanced in bypass patients.

Intestinal bacterial overgrowth, with abnormal intestinal metabolism by bacteria of ingested nutrients and bile acids, could contribute to hepatic disease after bypass surgery via the production of endogenous hepatotoxins.

JEJUNO-ILEAL bypass is a highly effective treatment for selected patients with gross refractory obesity, but this operation may be followed by a variety of complications. In addition to anticipated nutritional disturbances, there are a number of unexplained sequelae including arthralgia, colonic pseudo-obstruction and liver disease. In most cases the hepatic disturbance, characterized by hepatic steatosis and patchy hepatocellular necrosis, is subclinical. However, death from hepatic failure has been reported in between 2 and 8 per cent of patients (Maxwell et al., 1977). While bacteria have been implicated in the arthralgia and colonic pseudo-obstruction following bypass surgery (Wands et al., 1976; Barry et al., 1977), the pathogenesis of liver disease, the most serious complication of this operation, remainds unexplained.

In previous studies neither hepatitis B infection nor halothane anaesthesia could be implicated (Maxwell et al., 1977). Although nutritional disturbances may contribute, there is no simple relationship between altered liver function and weight loss following bypass (Salmon and Reedyk, 1975). As abnormal intestinal bacterial metabolism of ingested nutrients and bile acids might be relevant to post-bypass hepatic dysfunction, we studied the effects of jejuno-ileal bypass on the bacterial flora in the jejunum proximal to the excluded segment, and on the bacterial metabolism of tryptophan and bile acids within the intestine.

Patients and methods

Twelve unselected patients (all female, aged 28–64 years) were investigated at least 3 years after jejuno-ileal bypass surgery as part of a routine postoperative evaluation. The operation performed was a modification of the standard procedure. Four inches (10 cm) of jejunum measured from the duodenojejunal junction were anastomosed end to side to the terminal 10 in (25 cm) of ileum, thus producing an isoperistaltic excluded segment of jejuno-ileum several feet in length. None of the bypass patients had any clinical or biochemical features of liver disease at the time of study. However, liver biopsy revealed extensive fatty change, together with variable degrees of patchy focal necrosis, portal tract hypercellularity and parenchymal fibrosis, in all patients.

Five control subjects, matched for age and sex, were selected from obese patients awaiting jejuno-ileal bypass surgery and from hospital inpatients. None of the controls had undergone bowel surgery, nor had any of the patients or controls recently received any antibiotic therapy. The nature of the study was explained, and all subjects gave informed consent before investigation.

The following investigations were performed:

Jejunal aspiration: A jejunal aspirate was obtained from the fasting subject by passing a sterile Andersen radio-opaque long weighted sump tube transnasally and positioning it, under radiological control, just distal to the duodenojejunal flexure. Two millilitres of jejunal contents were aspirated into a sterile syringe, any air was excluded and the syringe was made airtight with a cap. Samples were transported to the laboratory where they were either cultured immediately or frozen for culture at a later date. Aliquots (1 ml) of samples to be frozen were injected into a carbon dioxide gassed vial containing 9 ml of 10 per cent glycerol broth. The vial was then immersed in a methanol/acetone/solid CO_2 mixture in a vacuum flask. Frozen samples were stored at −20 °C and cultured within 3 weeks.

Aerobic/anaerobic bacterial culture: Serial logarithmic dilutions of the aspirate were made in brain–heart infusion broth up to 10^{-8}. Equal volumes of each dilution (0·1 ml) were spread on to a series of selective and non-selective media and incubated under appropriate atmospheric conditions for up to 5 days. Bacterial counts and identifications of species were carried out according to standard methods as described by Holderman and Moore (1972) and Cowan and Steel (1974).

Bile acids in postprandial bile: After obtaining the initial fasting jejunal aspirate for bacterial culture, the patient was given a standard Lundh test meal to stimulate bile secretion. Bile was siphoned off for 2 h into a sterile bottle kept on ice. Samples were stored at −20 °C before analysis for deconjugated bile acids by thin-layer chromatography. This was carried out on 0·25 mm silica gel plates developed with solvent systems using trimethylpentane : ethylacetate : acetic acid (5 : 5 : 1) and benzene : isopropanol : acetic acid (30 : 10 : 1) (Eneroth, 1963).

Bile acid breath test: Hourly breath samples were collected into hyamine hydroxide for 8 h after oral administration of 5 μCi ^{14}C-glycocholate with a Lundh test meal after an overnight fast. No jejunal fluid was aspirated on this occasion. ^{14}C radioactivity was measured by liquid scintillation counter and expressed as a percentage of the dose given per mmol $CO_2 \times$ body weight (kilogrammes) (James et al., 1973).

Urinary indican excretion: Urine was collected for 24 h into bottles containing thymol as preservative. All subjects were on a normal diet, taking 60–100 g protein daily. The indican content was measured by the spectrophotometric method of Curzon and Walsh (1962). Urinary creatinine excretion was also measured to evaluate the completeness of urine collection.

Results

Bacterial culture

Counts of aerobic organisms in the group of 12 post-bypass patients were higher than in the group of 5

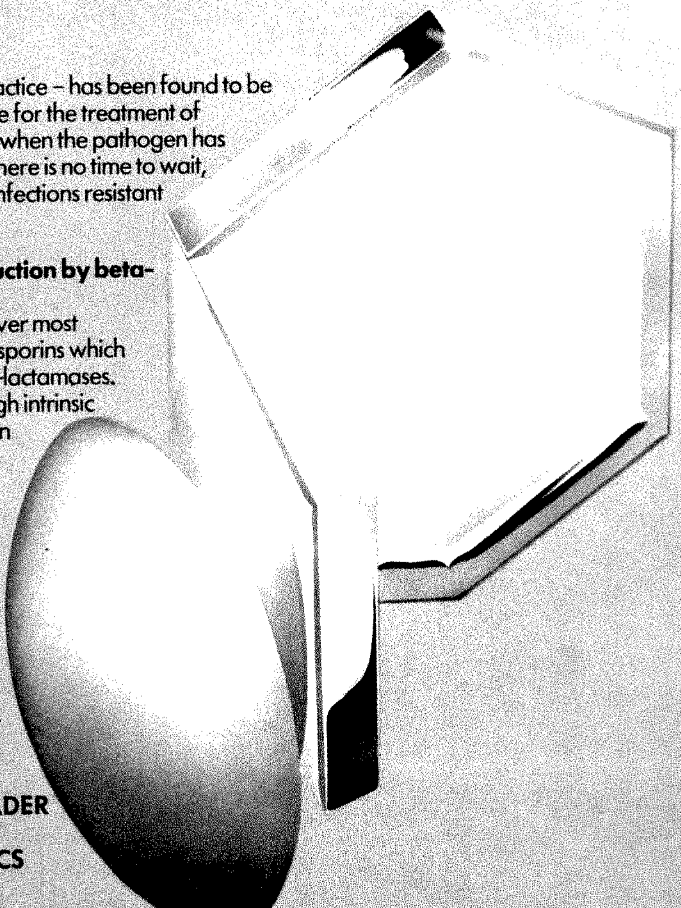
A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Already used widely in serious infections

INJECTABLE

ZINACEF

cefuroxime sodium



Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics..

Zinacef resists destruction by beta-lactamases
A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.

Zinacef is effective against:

- **most common pathogens**
- **many uncommon pathogens**
- **multi-antibiotic resistant pathogens**

ZINACEF, A BROADER SPECTRUM THAN MOST ANTIBIOTICS

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 grams and infusion pack of 1·5 grams. All containing cefuroxime as cefuroxime sodium.
Indications
Serious bacterial infections, especially where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft-tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Ear, nose and throat infections
Meningitis
Gonorrhoea
Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 grams t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary, giving total doses of 3 grams to 6 grams daily.
Infants and Children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 grams (2 x 750mg i.m. into different sites).
Contra-indications
Hypersensitivity to cephalosporins.
Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria. Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.
Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro-intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).
Storage
Protect from light.
Product Licence number: 4/0253
Price to Hospital (exclusive of VAT):

5 x 250mg	£0·70 per vial
5 x 750mg	£2·10 per vial
1·5 grams	£4·20

mightier than the knife

Now there is a practical alternative to surgery for calcium renal lithiasis: long-term prophylaxis with Zyloric.

Zyloric has proved effective in preventing and treating calcium renal lithiasis in patients with raised serum or urinary uric acid.

In a recent trial,[1] 48 patients with hyperuricosuria were treated with Zyloric for an average of 3.88 patient-years. The number of renal stones predicted for this period was 94.9. The actual number of stones formed was 8. Prior to treatment with Zyloric, half of these patients were hospitalised because of stone disease.

A leading article[2] in the *British Medical Journal*, commenting on another clinical paper[3] stated "...the only criterion of success in the treatment of calcium stone disease is total cessation of stone formation. By this criterion, allopurinol (Zyloric) was greatly superior to the placebo."

[1] *Ann. intern. Med.* (1977), **87**, 404. [2] *Brit. med J.* (1977), **2**, 1302. [3] *J. Urol.* (1977) **117**, 690.

ZYLORIC-300

allopurinol BP Wellcome

stops renal stones starting

Indications: Conditions of excess body urate including gouty arthritis. Prophylaxis of calcium renal lithiasis in patients with raised serum or urinary uric acid.
Dosage: The average adult dose is one Zyloric-300 tablet daily, plus an anti-inflammatory agent or colchicine for at least one month. Dosage should be adjusted by monitoring serum uric acid until the required level is attained. It has rarely been found necessary to exceed 900 mg per day. Children: 10-20 mg/kg bodyweight/day.
Contra-indications: None, other than known intolerance to Zyloric. **Precautions:** If Puri-Nethol* (6-mercaptopurine) or Imuran* (azathioprine) is given concurrently with Zyloric, the dose of Puri-Nethol or Imuran should be reduced to one quarter of the usual dose. Caution should be observed in pregnancy. Zyloric is not a treatment for acute gout, but prophylactic treatment with Zyloric may be started at the same time as anti-inflammatory treatment. **Side-effects:** These are usually rare and mostly of a minor nature. They include skin reactions, generalised hypersensitivity, gastro-intestinal disorders, blood and lymphatic disorders. **Presentation:** Zyloric-300* is available as 300 mg scored, creamy-white tablets in packs of 28. Basic NHS cost: £5.96 per pack. PL 3/0092. Also available: 100 mg tablets in bottles of 100. Additional information about Zyloric* (allopurinol) is available on request.

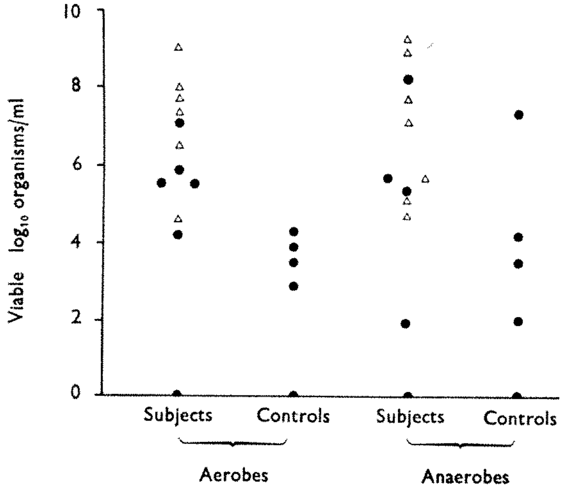

Fig. 1. Log counts of aerobic and anaerobic organisms from proximal jejunal aspirates in post-bypass patients and controls. ●, Small intestinal flora. △, Colonic flora.

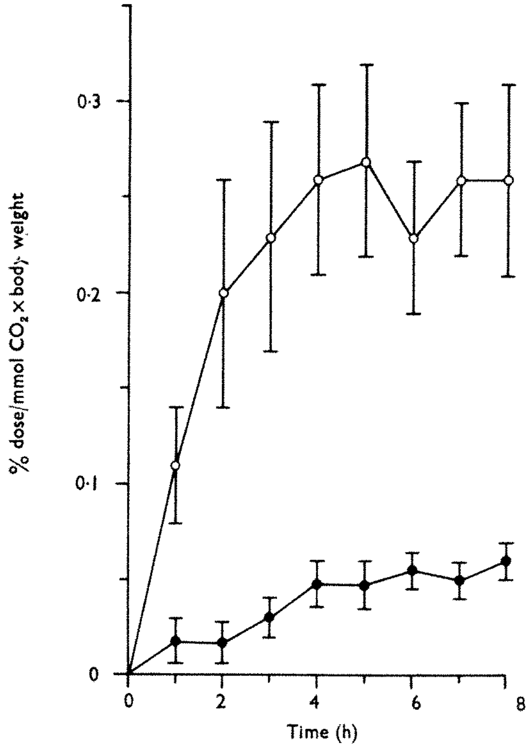

Fig. 2. Bile acid breath test in post-bypass patients (○) and controls (●). All results given as mean ± s.e. mean.

control subjects ($P<0·02$, Mann–Whitney U test). Counts of anaerobic organisms in the two groups were not significantly different ($P>0·05$, Mann–Whitney U test) (*Fig.* 1).

A separate estimation was made regarding the presence or absence of colonic flora in jejunal aspirates. Aerobic colonic flora were present in 6 of the post-bypass patients but in none of the controls ($P=0·075$, Fisher's exact test). Anaerobic colonic flora were present in 7 of the post-bypass patients but in none of the controls ($P=0·04$, Fisher's exact test). Aerobic and/or anaerobic colonic flora was present in 8 of the post-bypass patients but in none of the controls ($P=0·02$, Fisher's exact test).

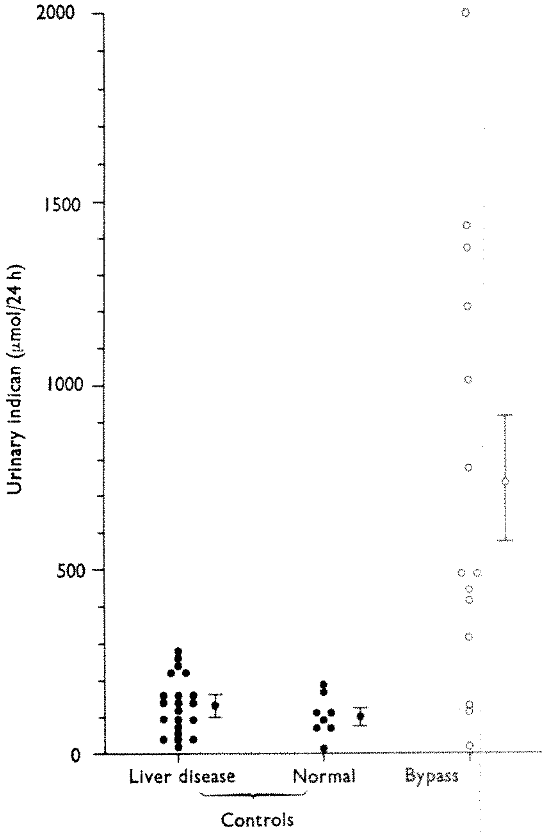

Fig. 3. Urinary indican excretion (μmol/24 h) in post-bypass patients (○), normal controls and liver disease controls (●). All results given as mean ± s.e. mean.

Neither subjects nor controls had aerobic bacteria which could deconjugate bile salts. Ten out of 12 subjects and 4 out of five controls had anaerobic bacteria which could deconjugate bile salts. In the control group only one species was present which could deconjugate bile salts, i.e. veillonella. However, in the group of subjects, a variety of deconjugating bacteria was present. These included bacteroides, veillonellae, bifidobacteria and other anaerobic Gram-positive rods. More than one species was often present in each of the subjects.

Thin-layer chromatography

Thin-layer chromatography using two different solvent systems showed the presence of deconjugated bile acid in jejunal aspirate from 2 of the 12 post-bypass patients. One patient showed the presence of deconjugated deoxycholic acid and the other showed deconjugated cholic acid, chenodeoxycholic acid and deoxycholic acid.

Bile acid breath test

There was increased deconjugation of bile acids in the group of 11 post-bypass patients compared with the group of 11 normal control subjects ($P<0{\cdot}001$, Student's *t* test) (*Fig.* 2).

Urinary indican excretion

Urinary indican excretion was higher in the group of 15 post-bypass patients compared with the group of 21 liver disease control patients ($P<0{\cdot}001$, Student's *t* test) and with the group of 15 normal control subjects ($P<0{\cdot}01$, Student's *t* test) (*Fig.* 3).

Discussion

These studies have clearly demonstrated bacterial overgrowth in the proximal jejunum in the majority of patients after jejuno-ileal bypass. Elevated counts of aerobes and/or anaerobes were found in 10 of 12 subjects and in 8 of these the flora was colonic in type.

These results are in keeping with previous reports that bacterial colonization of the small bowel occurs following bypass (Dano et al., 1974; Barry et al., 1977), but the mode of colonization is uncertain. The bacterial overgrowth with a flora that is often colonic in type may be related to the proximity of the jejunum to the ileocaecal valve, and is similar to that found following massive small intestinal resection (Kristensen et al., 1974). Alternatively, the proximity of the surgically produced anatomical blind loop may contribute to bacterial colonization in the proximal jejunum. Although isoperistaltically emptying segments are not generally considered to function as blind loops (Donaldson, 1965), the extreme lengths of the bypassed loop may invalidate this assumption (Brown et al., 1974).

The presence of an abnormal jejunal flora in the majority of patients was accompanied by evidence of abnormal intestinal metabolism of bile salts and protein in all subjects studied after bypass. It is of interest that many of the bacterial species identified from jejunal aspirates in these subjects are known to be capable of deconjugating bile salts (Drasar and Hill, 1974). From the present studies we are unable to distinguish the relative contribution of the residual small intestine left in circuit, the bypassed segment or the colon to the intestinal metabolism we have demonstrated. However, as deconjugated bile acids were present in jejunal aspirate from only a minority of patients studied, it is likely that intestinal bacterial metabolism of bile salts and nutrients takes place largely at more distal sites.

Although intestinal bacteria have been implicated in the arthralgia and colonic pseudo-obstruction that may occasionally complicate intestinal bypass, their role in the development of post-bypass hepatic dysfunction is less well established. Experimental animal studies investigating the effect of antibacterial drugs on the development of hepatic changes after intestinal bypass have produced conflicting results (McClelland et al., 1970; Hollenbeck et al., 1975). However, it is of interest that in both the dog and the rat, liver function appears to be more disturbed after bypass than after comparable resection (Hollenbeck et al., 1975; Rutter et al., 1978).

The pathogenesis of liver dysfunction after intestinal bypass is almost certainly multifactorial. Nevertheless, our clinical studies provide some indirect evidence for the involvement of bacteria. Intestinal bacterial metabolism of proteins and amino acids, which we have demonstrated indirectly from elevated urinary indican excretion, may contribute to the hypoproteinaemia and deficiencies in circulating amino-acids which have been observed after bypass (Moxley et al., 1974). Moreover, protein deficiency enhances the hepatotoxic effect of bile acids (Carey et al., 1966) and alcohol (Lieber, 1974).

The striking intestinal deconjugation of bile acids that we have demonstrated could provide an explanation for the earlier observation that grossly elevated serum levels of deconjugated bile acids, including lithocholic acid, a known hepatotoxin, occur after bypass (Sherr et al., 1974). Furthermore, there is evidence that small quantities of alcohol are produced by these patients (Mezey et al., 1975), presumably by intestinal bacterial fermentation of ingested carbohydrate. This finding may be relevant to the close histological similarity between the hepatic changes occurring after jejuno-ileal bypass and those found in alcoholic liver disease (Peters et al., 1975).

Thus it seems possible that bacterial metabolism of ingested nutrients and bile acids within the intestine may contribute not only to the nutritional disturbance but also to the hepatic disease which is an almost universal sequel to intestinal bypass. If this suggestion is confirmed by further investigation, there is a prospect of rational treatment or prophylaxis for the major complication of jejuno-ileal bypass surgery.

The effect of bile acids on colonic myoelectrical activity

M. FLYNN, C. DARBY, J. HYLAND, P. HAMMOND AND I. TAYLOR*

SUMMARY

The effect of different concentrations of sodium cholate, sodium chenodeoxycholate and sodium deoxycholate on colonic myoelectrical activity was studied in 4 dogs. There was no statistically significant difference in percentage motility, motility index, basal pressure or mean slow wave frequency with either cholic or chenodeoxycholic acid (5–15 mM). Deoxycholic acid (15 mM), however, caused a marked increase in percentage motility (median control value 4·1, range 0–23; after installation, median value 27·0, range 20·6–45·0, P<0·001). This was accompanied by an increase in spike activity, but no alteration in mean slow wave frequency or basal pressure was seen. Cholestyramine inhibited the motor response. It appears that only deoxycholic acid affects both motility and absorption, presumably by different pathways, and may thus assume importance in disorders of colonic motility.

THE role of bile acids as an aetiological factor in the disorders of colonic motility remains controversial. The enterohepatic circulation ensures that bile acids secreted by the liver are absorbed from the small intestine and only small amounts of chenodeoxycholic and cholic acid enter the colon. It is well known that after extensive small bowel resection increased amounts of bile acids reach the colon and the resultant watery diarrhoea which occurs has been explained by decreased absorption of sodium, bicarbonate and water mediated through cyclic AMP (Hafkenschild, 1977). This sequence can be prevented by cholestyramine (Duncombe et al., 1977).

Diarrhoea frequently occurs in motor disorders of the colon, particularly in the irritable colon syndrome. However, the relationship between bile acids and motor function rather than absorptive function is not clear. Early reports suggested that bile acids inhibited contractions of isolated smooth muscle strips (Schwartz and Magerl, 1924), whereas *in vivo* they produced stimulation (Haney et al., 1939). Kirwan et al. (1975) described increased motility with sodium glycocholate and sodium deoxycholate in rabbits and sodium chenodeoxycholate and sodium taurocholate in man. Other workers suggested that primary bile acids have no significant effect on colonic motility (Falconer et al., 1978).

In this study we have measured the effects of the sodium salts of free bile acids (cholic, chenodeoxycholic and deoxycholic) on colonic motility in the dog. Initial studies have shown that the myoelectrical function of dog colon is similar to that in man. The effect of varying concentrations of each bile acid was assessed.

Materials and methods

Four dogs were studied (weight 15–20 kg). Thiry–Vella loops approximately 20 cm long were fashioned in each. Two silver/silver-chloride electrodes were sutured on to the serosa 15 cm apart and similar electrodes were placed proximal and distal to the colonic anastomosis (*Fig.* 1). The electrode wires were implanted subcutaneously so that they could be used for subsequent myoelectrical recordings. All recordings were carried out at least 2 weeks following operation.

The electrodes were connected to smooth muscle amplifiers and slow wave electrical activity recorded on a Devices pen recorder with an indifferent electrode on the left thigh.

Intraluminal pressure was recorded using a thin open-ended tube (1 mm internal diameter) placed within the loop. Modified Foley catheters ensured that the loop did not leak (*Fig.* 1). The tube was constantly perfused with 0·15 M saline at a rate of 0·2 ml/min using a perfusion pump. Pressure recordings were continuously displayed on the pen recorder.

Control recordings were performed before each experiment by introducing 5 ml of normal saline into the loop for a 30-min period. The following parameters were noted.

1. Pressure: (*a*) mean basal pressure (mmHg); (*b*) percentage motility—the proportion of recording time during which pressure waves were present.
2. Electrical activity: the mean slow wave frequency was recorded as well as the incidence of action potentials.

Following control recordings, the effect of varying pH and motility was noted by introducing 0·15 M phosphate-buffered saline at different pH values (6–10) into the loop and noting the responses. The osmolality of all bile acid solutions was comparable with 0·15 M saline.

Test solutions

Five-millilitre solutions of sodium deoxycholate, sodium cholate and sodium chenodeoxycholic (Maybridge Chemicals) were used in the study. Concentrations of between 5 and 15 mM were used and each solution was in the loop for a minimum of 20 min. The order was randomized for each experiment. At least two studies at each concentration were performed on different days in each dog.

The results for motility were calculated and analysed by non-parametric methods (Wilcoxon rank sum tests and area under standard curves).

Results

Control studies

The median percentage motility in the control studies was 9·0 per cent (range 0–50·0 mmHg). There was no statistically significant increase in motility following the introduction of solutions with varying pH.

Two slow wave electrical rhythms were recorded from the loop. The predominant one had a mean frequency of 0·215 ± 0·027 Hz (12·9 ± 1·6 c/m). The other had a slower frequency, 0·122 ± 0·005 Hz (7·3 ± 0·3 c/m) (*Fig.* 2). These mean frequencies were lower than those recorded from the proximal anastomosed colon—0·245 Hz (14·7 c/m) and 0·130 Hz (7·8 c/m)—reflecting the effect of transection on slow wave frequency.

Bile acids

Cholic and chenodeoxycholic acids: These bile acids produced no statistically significant increase in motility in the loop at concentrations of between 5 and 25 mM. The mean percentage motility following installation of each solution is shown in *Table I*.

The mean volume of each solution at the completion of the study was 5·5 ml. There was no statistically significant alteration in the mean slow wave frequency

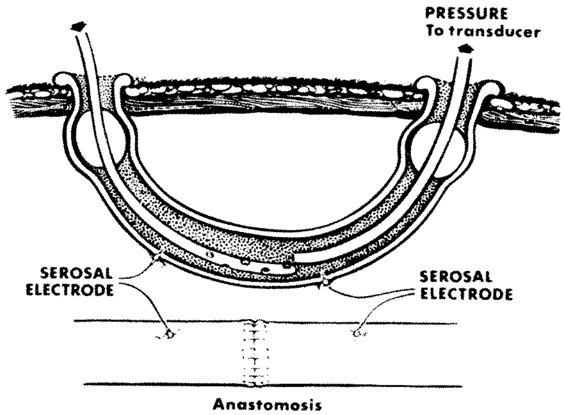

Fig. 1. Diagrammatic representation of Thiry–Vella loops in the dog showing the position of the serosal electrodes.

of either electrical rhythm and no increase in the incidence of action potentials.

Deoxycholic acid

Five and 10 mM deoxycholic acid had no statistically significant effect on motility. However, when given at a concentration of 15 mM there was a statistically significant increase in percentage motility ($P<0{\cdot}001$) (control, median 4·1 per cent, range 0–23 per cent; bile acids, median 27 per cent, range 20·6–45 per cent). The increase in motility occurred on each occasion (*Fig.* 3) and ceased on removal of the solution. This effect was inhibited by cholestyramine. The mean values are shown in *Table I*. The increase in motility had an onset time of 8–13 min and a duration of over 2 h.

There was no alteration in incidence or frequency of either electrical rhythm. Similarly, the increase in motility did not coincide with either rhythm but was noted when either was present. The incidence of action potentials increased and corresponded with the pressure waves (*Fig.* 3). There was no alteration in either slow wave frequency or action potentials in the proximal and distal anastomosed colon.

The colon was removed at the completion of each study and histological preparations showed no structural change in either mucosa or underlying smooth muscle.

Discussion

The efficient enterohepatic circulation allows only 5 per cent (approximately 700 mg) of bile acids to enter the colon each day (Samuel et al., 1968). In the colon anaerobic bacteria change the primary bile acids (cholic and chenodeoxycholic) into secondary forms (deoxycholic and lithocholic) by deconjugation and 7α-dehydroxylation. In the dog colon the dexoycholic acid concentration varies between 5 and 11 mM (in man between 5 and 15 mM).

Increased levels of these bile acids result in watery diarrhoea which could be due both to inhibition of Na^+/K^+ ATPase which reduces absorption of Na^+ ions and water, or to stimulation of cyclic AMP which increases secretion of water and electrolytes. The mechanism is analogous to the effects of cholera enterotoxin and prostaglandins (Conley et al., 1976; Hafkenschild, 1977).

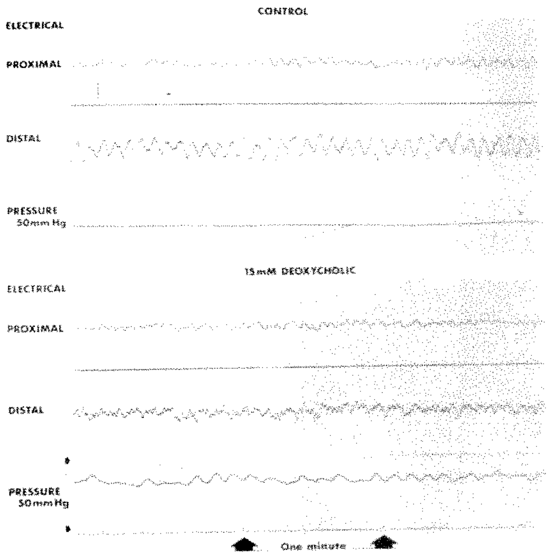

Fig. 2. Recordings of myoelectrical acitivity from the 'loop'. Top trace shows the control recording with a mean frequency of 12·1 c/m. Following the introduction of 15 mM deoxycholic acid into the loop the slow wave frequency is unaltered but action potentials are increased and the percentage motility correspondingly rises.

Table I: EFFECT OF BILE ACIDS ON PERCENTAGE MOTILITY

	Percentage motility	
Concentration	Median	Range
Cholic acid		
Control	12·5	0–50·0
5 mM	5·5	0–56·0 (n.s.)
10 mM	12·1	0–46·0 (n.s.)
15 mM	5·9	0–28·0 (n.s.)
Chenodeoxycholic acid		
Control	11·1	0–17·1
5 mM	4·5	0–9·0 (n.s.)
10 mM	0·8	0–15·8 (n.s.)
15 mM	4·5	0–22·0 (n.s.)
Deoxycholic acid		
Control	4·1	0–23·0
5 mM	13·6	0–35·0 (n.s.)
10 mM	8·6	0–22·0 (n.s.)
15 mM	27·0	20·6–45·0*

* $P<0{\cdot}001$.

Diarrhoea is a common symptom in motor disorders of the colon (particularly the irritable colon syndrome) and it may be that high levels of bile acids are a causative factor. If this is so, the absorptive effects of bile acids on the colon could explain the symptom of diarrhoea. Nevertheless, there is a myoelectrical disturbance in these patients (Taylor et al., 1978) and the role of bile acids in contributing to this motility abnormality has been investigated.

In our studies deoxycholic acid was the only bile acid shown to have a significant effect on colonic motility: indeed, this was seen to occur only at a concentration of 15 mM. However, all three bile acids (cholic, deoxycholic and chenodeoxycholic) have a definite inhibitory effect on absorption (Mekihjian and Phillips, 1970). It has been suggested that any

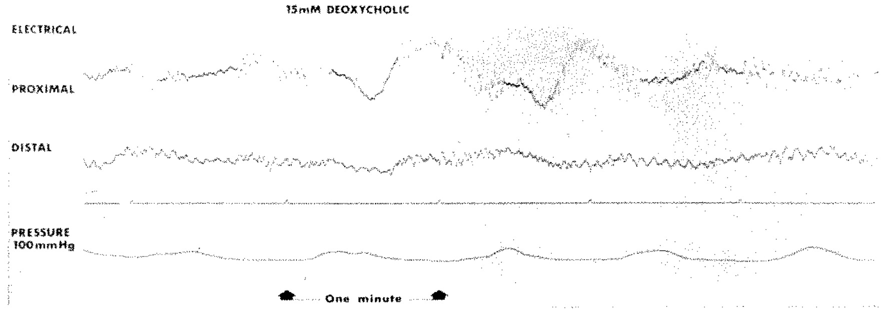

Fig. 3. Myoelectrical recording from the loop following the introduction of 15 mM deoxycholic acid. Note the significant increase in the incidence of action potentials and the corresponding pressure waves.

motor effect is secondary to the increase in intraluminal volume created by this inhibitory effect on absorption. This seems unlikely for two reasons: first, the change in volume created by 5–15-mM concentrations of bile acid was less than 10 per cent, which would not create such a large increase in motility, and secondly, if this were the entire explanation, all bile acids should have a similar action to 15 mM deoxycholic acid.

The increase in motility created by deoxycholic acid could be due to effects on the action of neurotransmitters of colonic smooth muscle either by an inhibitory effect at adrenergic sites or by enhancement of the action of acetylcholine on colonic smooth muscle. Falconer et al. (1978) suggest that deoxycholic acid stimulates smooth muscle contraction by mediating the release of prostaglandin E_2, and this effect can be inhibited by indomethacin. However, indomethacin has inhibitory effects on 5-hydroxytryptamine, bradykinin and histamine as well as prostaglandin E_2 (Sorrentino et al., 1972) and any of these compounds could be released by deoxycholic acid. Furthermore, the inhibitory action of indomethacin on smooth muscle has been interpreted in terms of inhibited Ca^{2+} ion uptake (Northover, 1971), possibly indicating that indomethacin inhibition of PGE_2 biosynthesis is secondary to its inhibition of smooth muscle contractions.

Deoxycholic acid may increase motility by increasing intracellular Ca^{2+} concentrations since slow waves and superimposed action potentials (or spikes) are dependent on Ca^{2+} ion levels (Grundfest, 1976). Evidence from studies on chick small intestine indicates that bile acids increase calcium ion absorption (Webling and Holdsworth, 1965) and work on rats suggests that Ca^{2+} ion absorption can be increased in the colon (Harrison and Harrison, 1969; Petith and Schedl, 1976).

Increased calcium absorption following the action of deoxycholic acid may occur in a number of ways:

1. By increasing membrane permeability in a similar way to acetylcholine (Szursewski, 1973).
2. By inhibition of an electrogenic calcium pump. Deoxycholic acid, unlike the primary bile acids, will effect Mg^{2+}-dependent ATPase and Mg^{2+} absorption is similar to that of Ca^{2+} (Hafkenschild, 1977).
3. By increasing the solubility of insoluble calcium salts found in the colon.
4. By binding Ca^{2+} ions and entering the cell as a calcium–bile acid complex.

Further studies are now being undertaken on Ca^{2+} absorption and bile acids in the colon.

It thus appears that any effect of bile acids on colonic motility is specific to deoxycholic acid at a slightly higher level than normal physiological concentrations. This response appears to be an 'all or nothing relationship' in that concentrations of less than 15 mM have no significant effect on motility whereas concentrations greater than this cause an increase in motility. This may explain some of the features encountered in motor disorders of the colon.

Reversed rotation of the mid gut: case reports

K. M. DESAI*

Case 1: A 64-year-old woman presented on 18 July 1978 with a clinical and radiological picture suggestive of caecal volvulus (*Fig.* 1). Laparotomy revealed a clockwise volvulus of the caecum and ascending colon through 360°. It was untwisted and the large bowel distal to the hepatic flexure pursued a course along the posterior abdominal wall dorsal to the small intestine and its mesentery to the origin of the superior mesenteric artery, to reappear in the left upper quadrant of the abdomen, where the left side of the transverse colon was in its normal relationship to the stomach and great omentum. Beyond this point the large bowel pursued a normal course. The great omentum passed direct from the stomach to become adherent over loops of small bowel. The descending portion of the duodenum passed straight down into the jejunum in front of the origin of the superior mesenteric artery. After deflation and derotation the bowel was returned to the abdomen. The patient made an uneventful recovery.

Case 2: A 79-year-old man was admitted to hospital as an emergency on 31 December 1949 with evidence of spreading lower abdominal peritonitis. At laparotomy the peritonitis was found to be due to perforated sigmoid diverticulitis. The treatment proposed was peritoneal toilet and drainage, with defunctioning transverse colostomy, but the transverse colon could not be found in the normal position. Further exploration revealed anatomy similar to that of *Case* 1. The splenic flexure was normally located, but the transverse colon ran posterior to the duodenojejunal junction and the superior mesenteric artery. The great omentum, devoid of colon, passed straight from the greater curvature of the stomach to lie over the small bowel. A diagnosis of reversed mid gut rotation was made and colostomy was omitted. The patient died of a cerebrovascular accident on the third postoperative day.

Anomalous intestinal rotation has been well documented by various authors including Dott (1923), Haymond and Dragstedt (1931), Gardner and Hart (1934), McIntosh and Donovan (1939) and Snyder and Chaffin (1954). Reversed rotation is rare. Davies et al., in a review article in 1955, found only 31 cases in the literature. In 7 of these the anomalous rotation was encountered incidentally at laparotomy for other conditions or at post-mortem: the other 24 had presented as intestinal obstruction. Wang and Welch (1963), reviewing 50 cases of abnormal rotation, cited only one instance of reversed rotation.

Chylous ascites and obstructive lymphoedema of the small bowel following abdominal radiotherapy

P. A. HURST AND J. M. EDWARDS*

SUMMARY

The case history of a patient who developed chylous ascites following abdominal irradiation for recurrent carcinoma of the colon is presented. Laparotomy revealed generalized radiation damage of the small bowel with a particularly severely affected segment of jejunum, from the serosal surface of which chyle was seen to be leaking. Mesenteric lymphangiography revealed an obstruction to lymphatic drainage in the mesentery. Resection of the worst affected segment of bowel prevented further development of chylous ascites.

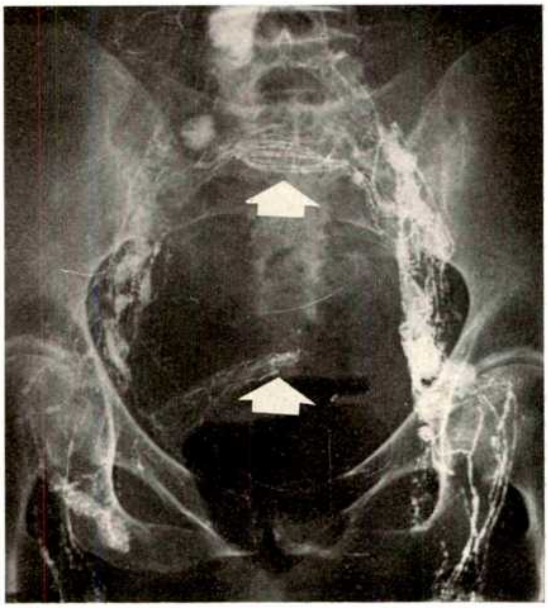

Fig. 1. Bipedal lymphangiogram performed following the development of chylous ascites 18 months after irradiation to the para-aortic nodes. Note the presence of abnormal collateral lymph channels around the bladder and in the presacral area (arrows) indicating proximal lymphatic obstruction. There is no evidence of residual para-aortic nodes or chylous leakage. Two calcified lymph nodes are present in the mesentery.

Case report

A 71-year-old housewife underwent left hemicolectomy for carcinoma of the sigmoid colon (J. M. E.). There were lymphatic metastases up to and including the para-aortic nodes. Histology revealed a well-differentiated adenocarcinoma. Recovery was uneventful and the patient was well until 18 months later when she presented with abdominal pain. On examination there was a palpable mass in the epigastrium and lymphography showed this to be due to secondary tumour in the para-aortic nodes. She received a course of radiotherapy, consisting of 4481 rad to the para-aortic nodes and 4499 rad to the pelvic nodes over 38 days using 8 meV and this was followed by a course of chemotherapy. Methyl CCNU 210 mg stat, 5FU 430 mg daily for 5 days and DIC 100 mg/m^2 daily for 5 days. This regimen was repeated twice at 2-monthly intervals and there was good clinical response with reduction in size of the epigastric mass. However, the patient then developed thrombocytopenia (platelets 10 400 mm^3) and presented as an emergency with gastrointestinal bleeding, passing melaena stools. Her haemoglobin fell to 5·5 g/dl but she responded well to blood transfusion and her bleeding ceased spontaneously. Liver ultrasound and barium enema at this time failed to reveal any residual tumour deposits. She was readmitted 1 month later with a further melaena associated with a haemoglobin level of 5·0 g/dl and a platelet count of 240 000/mm^3. After resuscitation the patient improved but bleeding continued and necessitated laparotomy. At operation gastrotomy was performed and this showed multiple mucosal bleeding points, presumed to be due to radiation gastritis. A high Polya partial gastrectomy was performed. The small bowel was found to be thickened and oedematous but there was no palpable evidence of residual tumour in the para-aortic nodes, nor of metastases in the liver. Her postoperative course was uneventful despite surgery on irradiated tissue.

Three years after hemicolectomy (18 months after radiotherapy), the patient developed ascites and this was initially thought to be malignant. However, paracentesis yielded 2 l of chylous fluid, analysis of which revealed chylomicrons but no malignant cells. Bipedal lymphography (*Fig.* 1) revealed no evidence of para-aortic node involvement. There was evidence of collateral lymphatic pathways (e.g. around the bladder) which had developed, presumably, as a result of proximal lymphatic obstruction.

Following 48 h of high fat diet (to show up chylous leakage) a laparotomy was performed through a right paramedian incision (J. M. E.). There were dense adhesions and most of the small bowel was found to be thickened and oedematous, with serosal telangiectasia and subserosal inclusion chylous cysts. One segment of jejunum was particularly severely involved and distended lymphatics full of chyle were visible on the serosa from which chyle oozed freely (*Fig.* 2).

A mesenteric lymphogram was performed by cannulation of a distended serosal lymphatic and the infusion of Lipiodol Ultra-Fluid (*Fig.* 3). No flow into the lymphatics in the mesentery occurred but back flow of contrast medium filled the lymphatics in the bowel wall (*Fig.* 4). No Lipiodol reached the cisterna or thoracic duct. The lymphatic block was presumably due to radiation fibrosis in the mesentery.

The worst affected segment of jejunum (some 20 cm in length) and its mesentery was resected and the remaining bowel was anastomosed in two layers. Histology of the resected bowel revealed the typical changes of irradiation with submucosal fibrosis, arterial sclerosis and marked lymphatic ectasia (*Fig.* 5). In the year following this operation the ascites has not recurred.

Discussion

The development of chylous ascites following radiation therapy for ovarian carcinoma was reported by Murray and Massey in 1974. They successfully treated 3 cases with medium chain triglyceride diet after excluding recurrent disease at laparotomy. This diet is extremely unpalatable and is poorly tolerated.

The findings at mesenteric lymphangiography in this case confirm the suggestion made by Jackson (1976) that there is obstruction to the normal flow in the mesenteric lymphatics secondary to radiation damage. The backfilling of lymphatics in the bowel wall (*Fig.* 4) may be likened to dermal backflow seen at pedal lymphography in obstructive lymphoedema

---

* Department of Surgery, St Thomas's Hospital, London.

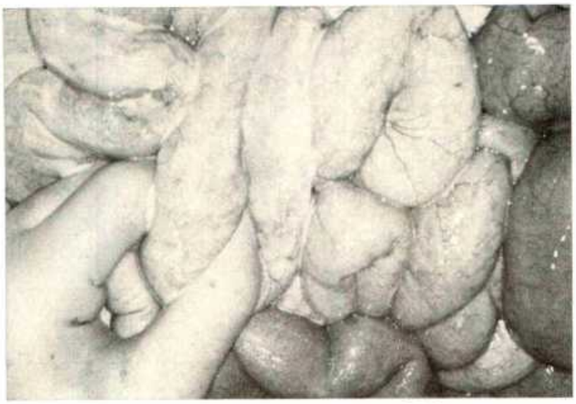

Fig. 2. The most severely affected segment of jejunum, showing chyle leaking from the serosa and post-radiation telangiectasia. Other loops of small bowel are less damaged.

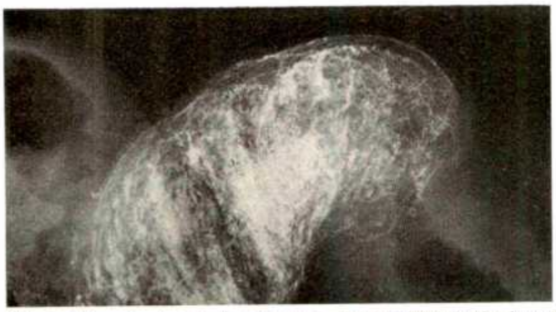

Fig. 3. Mesenteric lymphangiogram. Lymphatics in the bowel wall are filled but there is no filling of mesenteric lymphatics, nor of mesenteric nodes. (The nodes seen are iliac nodes still filled with Lipiodol from previous lymphography and calcified mesenteric nodes.)

of the limbs. A similar mesenteric lymphangiographic appearance was seen by Kinmonth and Cox (1974) in patients with protein-losing enteropathy in primary lymphoedema. They found that these patients leak chyle from the serosal surface of the bowel and that the chylous ascites was markedly improved by surgical excision of the worst affected bowel. Applying the same principles to this case we excised the most severely affected segment of jejunum, and no further chylous ascites has developed 1 year after operation. The histology of the resected bowel showed distended submucosal lymphatics as reported by Warren and Freidman in 1941. This lymphatic distension can be explained on the basis of obstruction to mesenteric lymphatic drainage as revealed by mesenteric lymphangiography.

This case history is of importance in showing that ascites occurring after abdominal radiation may in some instances be due not to malignancy but to lymphatic block in the mesentery. Diagnostic tap should always be performed and if chylous ascites is found laparotomy should follow as resection of severely affected bowel may prevent accumulation of further chylous ascites.

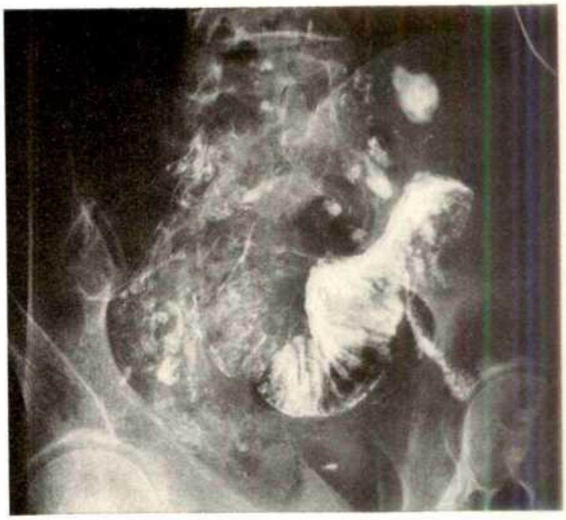

Fig. 4. High definition X-ray of jejunum showing backfilling of lymphatics in the bowel wall due to obstruction of lymphatics in the mesentery.

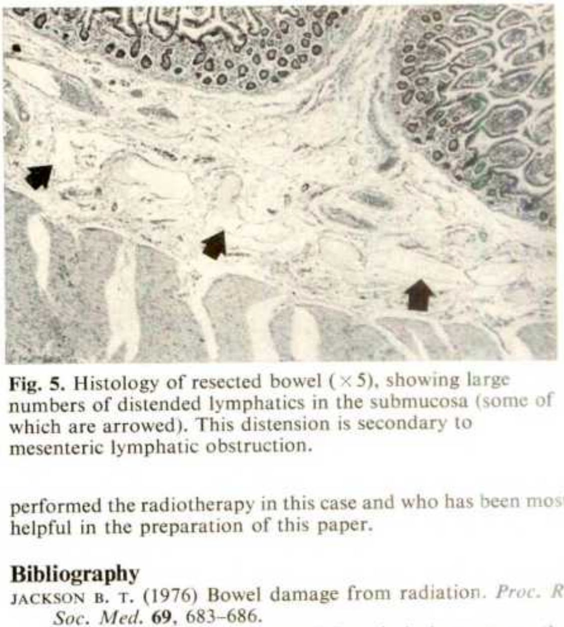

Fig. 5. Histology of resected bowel (× 5), showing large numbers of distended lymphatics in the submucosa (some of which are arrowed). This distension is secondary to mesenteric lymphatic obstruction.

Leucocyte counts in the diagnosis and prognosis of acute appendicitis in children

N. V. DORAISWAMY*

SUMMARY

Preoperative total and differential leucocyte counts were made in 225 children with acute appendicitis, 50 children with a normal appendix and 100 children with acute abdominal pain which resolved without any therapy. When adjusted to age, neutrophilia in 96 per cent, 30 per cent and 32 per cent and leucocytosis in 41·8 per cent, 4 per cent and 3 per cent was noted in the respective groups, the levels being significantly higher in the acute appendicitis group than in the other two groups. Among children with appendicitis, infections were observed in 62·8 per cent of the group with leucocytosis and in 13·7 per cent of the group with a normal leucocyte count; the difference is statistically significant. It is suggested that in acute appendicitis neutrophilia supports the diagnosis and leucocytosis indicates the prognosis. The rate of infection increases as the total leucocyte count rises above the upper normal limit. The difference of opinions on the significance of leucocyte counts in acute appendicitis is discussed.

Table I: NORMAL UPPER LIMITS OF LEUCOCYTE COUNTS IN DIFFERENT AGE GROUPS

Age (yr)	Total leucocyte counts/dl	Neutrophils (%)
0–5	15 000	50
5–10	15 000	65
10–15	13 000	75

Table II: RAISED LEUCOCYTE COUNTS IN THE GROUPS STUDIED

		Raised counts	
Group	No. of cases	Total leucocytes	Neutrophil percentage
Acute appendicitis	225	94 (41·8)	216 (96)
Normal appendix	50	2 (4·0)	15 (30)
Abdominal pain	100	3 (3·0)	32 (32)
Total	315	99	263

Figures in brackets are percentages of total patients.

Leucocyte counts are commonly performed during the assessment of patients suspected of having acute appendicitis and the experience recorded here gives an indication of their value in both diagnosis and prognosis.

Patients and methods

Before operation total and differential leucocyte counts were made on 225 children with acute appendicitis, 50 children in whom, following a clinical diagnosis of acute appendicitis, normal appendices without any other inflammatory lesion were found at laparotomy and 100 children with acute abdominal pain and who recovered without any specific therapy. Children between the ages of 5 and 15 were included in this study. The total leucocyte counts were performed using the Coulter cell counter. The incidence of postoperative abdominal infective complications was recorded. Children with extra-abdominal complications were excluded. Student's *t* test was used for statistical analysis of results and the χ^2 test was used for the data in *Table IV*.

Results

Mann's values (1977) for normal leucocyte counts for children of varying ages have been used in this study (*Table I*). The raised total leucocyte counts and neutrophil percentages among the three groups have been tabulated according to age (*Table II*). A raised neutrophil percentage was noted in all children with a raised total leucocyte count and acute appendicitis and, furthermore, in all but 9 of the remaining children with acute appendicitis (and a normal total leucocyte count), i.e. 96 per cent. In the other two groups a raised neutrophil percentage was observed in 30 per cent and 32 per cent respectively.

The postoperative abdominal infection rate was compared in children with appendicitis to examine the relationship to the leucocyte count (*Fig.* 1). The total leucocyte count was raised in 94, 2 and 3 patients in the respective groups (*Table II*). In the appendicitis group as a whole 66 (29·3 per cent) children had abdominal infective complications with clearly recognizable localizing signs. A further 11 children (4·9 per cent) had fever persisting for more than a day and in the absence of evidence for the existence of infection elsewhere, this was attributed to incompletely resolved infection at the appendix site, thus making a total of 77 (34·2 per cent). Two children in the normal appendix group developed wound infection.

Discussion

The diagnosis of acute appendicitis rests mainly on the history and physical signs. Anxiety not to withhold operative treatment for a potentially serious illness weighs justifiably on the side of intervention in doubtful cases. Despite the indication of a strongly suggestive history with supporting physical signs, many series show that the appendix is found to be normal at about one-quarter of operations—28 per cent (Hobson and Rosenman, 1964), 20 per cent (Swink, 1969), 25 per cent (Jacob et al., 1975). There is a need for improvement in accuracy of clinical diagnosis.

Leucocyte counts are usually ordered to support the clinical diagnosis, but different opinions have been expressed on their significance—useful (Lansden, 1963), no specific value (Shepherd, 1968), misleading (Arnot, 1975), little part (Gilmore et al., 1975). In view of these different opinions, this study was undertaken to correlate the practical usefulness of leucocyte counts in acute appendicitis in children.

When leucocyte counts were analysed according to age (Doraiswamy, 1977), neutrophilia was observed in 216 (96 per cent) children with acute appendicitis but in only 15 (30 per cent) and 32 (32 per cent) children in the remaining two groups. Moreover the

1001–5000	25 (26·99)	18 (16·01)	43
> 5000	30 (21·97)	5 (13·03)	35
Total	59	35	94

Numbers in brackets are expected values.
$\chi^2 + 18{\cdot}05$ with 2 d.f.

results were highly significant ($P < 0{\cdot}001$) when the appendicitis group was compared with the other two groups. They indicate that a raised neutrophil percentage is a useful diagnostic aid to supplement the clinical diagnosis. Conversely, a diagnosis of acute appendicitis should be made with reservations when there is a normal neutrophil percentage. There was no significant difference for neutrophilia between the groups with a normal appendix or abdominal pain.

A significantly ($P < 0{\cdot}001$) raised total leucocyte count was observed in the appendicitis group when compared with the other two groups but there was no significance when the normal appendix group was compared with the abdominal pain group. However, 131 (58·2 per cent) children had a total leucocyte count in the normal range in the appendicitis group and therefore it is not as useful in supplementing the clinical diagnosis as the neutrophil percentage (*Fig.* 1).

The overall incidence of postoperative abdominal infective complications in this series was 34·2 per cent (77 patients) among those in the appendicitis group and 4 per cent in the normal appendix group, similar to the general experience (Editorial, 1971; Gilmore et al., 1975).

When the immunological mechanisms are normal, leucocytes are important for protecting against harmful agents including bacteria. Organisms in the lumen of the appendix (Doraiswamy et al., 1978) cause the infective complications of acute appendicitis (Doraiswamy, 1978) and secondary sepsis is counteracted by leucocytosis. The importance of the total leucocyte count in acute appendicitis is indicated in *Fig.* 1 which shows that among the 94 children who had a raised total leucocyte count, 62·8 per cent (48 + 11 patients) developed postoperative abdominal infective complications whereas only 13·7 per cent (18 patients) had such complications among the 131 children who had a normal total leucocyte count. This suggests that though infection can be met with when the total leucocyte count is normal, the incidence of infection is significantly ($P < 0{\cdot}001$) higher when the count is raised and hence it is a useful indicator of prognosis.

Table III shows that the incidence of infective complications rises in proportion to the leucocyte count. When the total leucocyte count exceeded 7000 cells/dl above the normal upper limit, it was noted that all children developed abdominal infections.

Table IV shows the relationship between the leucocyte count and the departure from the expected incidence of septic complications in acute appendicitis. It can be seen that as the total leucocyte count increases the incidence of infection increases. The χ^2 value is highly significant ($P < 0{\cdot}001$) and indicates that there is a relationship between leucocytosis and infection.

The contradictory opinions that have been expressed regarding the significance of leucocyte counts in the diagnosis of acute appendicitis are to be explained by the fact that most of these other reports were not analysed against the duration of the disease. It has been noted that the laboratory results, including leucocyte counts, differ according to the duration of the disease (Doraiswamy, 1978), raised total leucocyte counts being observed at a later stage of the disease when bacterial infection is established. Pinpointing the exact time of onset of the disease to correlate the prognosis presents a practical difficulty, but leucocyte counts can be made fairly accurately. It is easier to interpret prognosis in accordance with total leucocyte counts which reflect the incidence of bacterial infection than to recognize the exact time of onset and hence the duration of the disease. Moreover, other factors such as obstruction of the lumen of the appendix by faecoliths, administration of antibiotics and the general immunological status may also influence the rate of infection.

Conclusion

In acute appendicitis in children, when account is taken of age-related variation, the neutrophil percentage is raised in most cases and this finding supports a clinical diagnosis. When the neutrophil percentage is normal, however, a diagnosis of appendicitis should be made with reservation. A moderate rise in the total leucocyte count correlates with the incidence of postoperative abdominal infective complications, until at the level of 7000 cells/dl above the upper normal range infection is found constantly.

Heyer-Schulte Jackson-Pratt Suction Drain System

Soft and simple

The Jackson-Pratt Drain System has been proven in a wide variety of post-operative drainage procedures.

It's made with supple, silicone elastomer — unlike the more rigid devices that can cause trauma. And, it's available with round and flat suction drains, a T-tube drain and 100cc reservoir for connection to single or multiple drains.

CONTROL OF OEDEMA

The unique Cape STERISHIELD is the most effective technique yet devised for oedema and infection control following limb surgery.
The simpler Cape Pressure Environment Treatment has proved successful in treating both chronic and acute oedema of the limb.

Controlled environment therapy in the management of lymphoedema: a case report

ARTHUR McG. MORRIS AND GORDON W. MORRISON*

SUMMARY

A case of surgically-treated elephantiasis of a lower limb is reported in which preoperative controlled environment therapy (CET) proved to be an effective, rapid method of reducing the oedema.

Case report

A 67-year-old man presented with a 12-year history of gross swelling of the right lower leg (*Fig.* 1). There were extensive filiform growths of the dorsum of the foot, and *Myobacterium tuberculosis* was grown from a skin biopsy. When referred for surgery he had been on antituberculous chemotherapy for 1 year.

The patient was treated for 2 weeks with CET (Kegal, 1976). The CET machine, designed by the Biomedical Research and Development Unit (BRADU) and available from Cape Engineering Co. Ltd, Warwick, England, allows a limb to be exposed to sterile warm dried air while enclosed in a transparent polyvinyl chloride bag. Cycles of air under pressure are passed through the bag. In this case, the leg was placed in the largest available bag (*Fig.* 2), and exposed to pressures varying from 10 mmHg to 30 mmHg in 15- and 30-s spells, respectively. The treatment was continuous for 2 weeks.

The oedema subsided rapidly, and within a week the maximum calf circumference was reduced from 73 cm to 43 cm. Redundant skin fell posteriorly and formed a convenient fold for wedge excision of skin and subcutaneous tissues. At operation the dorsum of the foot was excised down to the level

of the extensor tendons. The toes were filleted and the bony skeleton amputated, as there was enlargement of the whole foot. The plantar skin of the toes was turned over to cover the dorsum of the distal forefoot, the remainder of the defect being covered with a split skin graft from the opposite thigh.

Four weeks after operation, CET was used for 10 days to reduce the oedema further, prior to fitting a knee length surgical boot. The quality of the skin graft improved noticeably during CET. The patient has now been symptom-free for 9 months after the operation.

Discussion

Initially developed for use in the limb stump immediately after amputation, CET has been used in many situations where oedema of a limb is a problem. Intermittent pneumatic compression of the lymphooedematous leg has been described before (Calnan et al., 1970; Allenby et al., 1973), but CET apparatus offers added advantages.

1. The limb is visible at all times as the bag is transparent.

2. Physiotherapy can be carried out easily under direct vision.

3. The passage of sterile, warmed, dry air allows great improvement in the condition of the skin.

Postoperatively, the initial result was maintained by continuous compression bandaging and a surgical knee length boot. CET can be included again, if necessary, to reduce any recurrence of oedema very rapidly.

A new vascularized bone graft transferred by microvascular anastomosis as a free flap

ROY SANDERS AND BRYAN J. MAYOU*

SUMMARY

We describe a new, versatile bone and soft tissue compound free flap which may be transferred quickly and simply and describe its use in the treatment of compound fracture of the tibia and fibula with non-union due to loss of bone. The iliac crest and overlying soft tissue is transferred to the leg in one stage by microvascular anastomosis of the deep circumflex iliac vessels to vessels in the leg.

OSTEOCYTES lying within the lacunae of conventional bone grafts die (Phemister, 1914; Abbott et al., 1947). If grafting is successful, bone becomes vascularized from its new bed and the lacunae become recolonized. However, if the bone graft is transferred with its own vascular supply, the osteocytes remain viable (Doi et al., 1977). These vascularized bone grafts heal better than the conventional grafts (Doi et al., 1977). However, their use in man has been limited by the availability of suitable donor sites (Taylor et al., 1975; Buncke et al., 1977). We report the use of the iliac crest as a donor site vascularized by the deep circumflex iliac artery. The soft tissues and skin overlying the crest are also supplied by this artery and may be optionally included with the bone.

Case report

A 29-year-old man who sustained a compound fracture of the tibia and fibula 9 months previously was left with a 4-cm bony defect in the middle third of the tibia and a corresponding skin defect and scarring measuring 8 × 6 cm (*Fig.* 1).

A flap of 10 × 8 cm centred over the iliac crest was raised with 4 cm of the crest attached. The origin of the deep circumflex iliac vessels was defined through an incision parallel to and just above the inguinal ligament and by division of the inguinal ligament immediately lateral to the deep external ring. The vessels were traced laterally to the point behind the anterior superior iliac spine where they pierced first the transversalis fascia and then the transversus abdominis muscle to continue along and behind the rim of the iliac crest. After division of the vessels at their origin from the external iliac artery the flap was transferred to fill the leg defect and the deep circumflex iliac vessels were anastomosed end to end to the posterior tibial vessels. These vessels were all about 3 mm in diameter. The skin immediately became pink and the bone bled freely. Postoperatively there was some superficial loss of skin but at no point was the bone exposed. Since the soft tissues were supplied by vessels from the iliac crest, their survival indicated continued vascularization of the graft. There was radiological union of graft and tibia at 4½ months (*Fig.* 2).

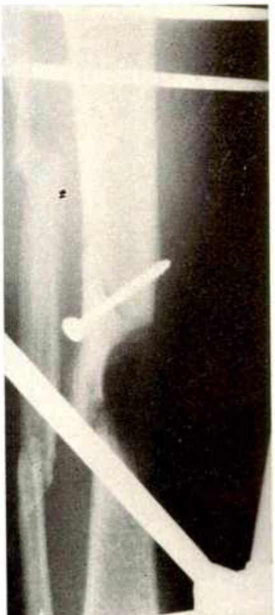

Fig. 1.

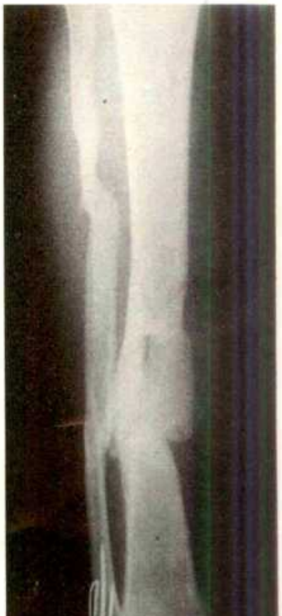

Fig. 2.

Fig. 1. A preoperative radiograph 9 months after injury showing the bones stabilized with Hoffman's external fixation and a bony defect.

Fig. 2. A radiograph of the leg 4½ months after surgery showing radiological union.

Discussion

The iliac crest based on the deep circumflex iliac vessels fulfils most of the requirements for a useful living bone graft. The bone is readily available and may be easily carved to size. The pedicle is long and consistent with vessels of wide diameter (artery 2·6–3·4 mm and vein 2·6–3·5 mm) (Mayou and Sanders, 1978). The soft tissues overlying the crest may be optionally included and the whole flap may be raised quickly and simply. Taylor and Watson (1978) have included the iliac crest with a free groin flap based on the superficial circumflex iliac vessels. However, these superficial vessels give little nourishment to the iliac crest and are of a small diameter (1·4 mm) with a short pedicle (Mayou and Sanders, 1978).

This living bone graft based on the deep circumflex vessels could be used without soft tissues in the treatment of non-union, where there is no bone loss but failure to heal after conventional bone grafting, and also in reconstruction, where bone is required sometimes with and sometimes without soft tissues, such as reconstruction of the mandible in congenital malformation, for gunshot wounds or after cancer extirpation.

The early diagnosis of ectopic pregnancy

GRAEME J. HUGHES*

SUMMARY

In a survey of 235 consecutive cases of ectopic pregnancy it was found that over 50 per cent were incorrectly diagnosed by the general practitioner and 36 per cent by a hospital doctor. Ten per cent of patients were sent home before the diagnosis was made.

Over 30 per cent of patients were sent to general surgical wards and these patients had different characteristics from those sent to gynaecological wards.

High risk patients can be identified from their past history. The increasing use of the laparoscope has been associated with earlier detection of ectopic pregnancy before the stage of rupture.

THERE is still a significant mortality in patients with ectopic pregnancy, and in the last maternal mortality report (Report on Confidential Enquiries into Maternal Deaths in England and Wales, 1972) 11 of the 34 deaths were considered to be avoidable. The incidence of ectopic pregnancy rose in Aberdeen until 1973 and since then has levelled off with some fluctuations (*Fig.* 1). It is important that all practitioners dealing with the disease should increase their awareness of the pitfalls in diagnosis and be able to identify high risk patients.

Patients and methods

Case notes of all women admitted to Aberdeen hospitals with ectopic pregnancy were studied over the years 1968 to 1977. Patients who had operations performed in non-gynaecological wards were also included in this study. The great majority of women in the Grampian region who had ectopic pregnancy diagnosed were sent to Aberdeen for surgery.

Results

Errors in diagnosis made by general practitioners

The diagnoses were obtained from the general practitioners' referral letters to the hospital. Some patients had no referral letter and others had no specific diagnosis mentioned (*Table I*).

The provisional diagnosis of ectopic pregnancy was only suggested in a minority of cases, and 1 in 5 patients was not even sent to a gynaecological ward. The initial diagnosis of the general practitioner was very important because it determined where the patient should be sent, and that in turn had a bearing on the type of investigation and treatment carried out. Some patients (19 per cent) were sent as non-emergencies to outpatient departments, sometimes surgical but usually gynaecological, for further assessment. Over 30 per cent were sent to surgical wards as emergencies. Three cases went to medical wards.

The incorrect provisional diagnoses made by the general practitioners are set out in *Table II*.

Errors in diagnosis at the outpatient department

Of those 44 patients who went to the outpatient department, 16 were not admitted as emergencies although most of them were given admission dates for further investigation.

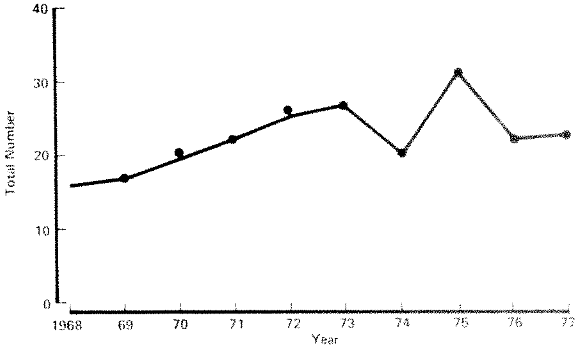

Fig. 1. Incidence of ectopic pregnancy 1968–77.

Errors in diagnosis after admission to hospital

The diagnoses shown in *Tables III* and *IV* were made prior to anaesthetic but with the aid of non-surgical investigations.

Almost 10 per cent of patients were sent home before the diagnosis of ectopic pregnancy was made, often having had a curettage for suspected incomplete or missed abortion. Occasionally the patients were recalled when histological examination of the curettings showed the Arias Stella reaction (florid secretory endometrium, typical of early pregnancy), but most returned with a ruptured ectopic pregnancy in a state of shock.

The type of wrong diagnosis depended on the ward to which the patient was sent. The common misdiagnosis in those sent to a gynaecological ward was spontaneous abortion or ovarian cyst, and in those sent to a surgical ward, appendicitis. Moreover, those women sent to surgical wards had different characteristics from those who were sent to gynaecological wards (*Table V*).

If the patient had an acute abdomen the general practitioner felt safer to admit her to a surgical ward, so most of the patients sent to surgical wards had ruptured ectopics and in most the ectopic was on the right side, giving the impression that it was appendicitis. Not surprisingly the correct diagnosis was more likely to be made if the patient had been admitted to a gynaecological ward than if the patient had been sent to a surgical ward.

Fig. 2 shows that the preoperative diagnosis of ectopic pregnancy is not becoming easier, probably because there are few non-surgical techniques to give much help.

Identifying the high risk group

Over 60 per cent of the patients in this series had one or more factors in their past history which are known to be associated with ectopic pregnancy.

The mean age in our series was 28. Previously it has been a disease of the third and fourth decades but more recently the mean age has been decreasing, and there were a surprising number of teenage girls. In 1968–9 36 per cent were older than 35 years, whereas

he molecular way to cleanse wounds: promote healing.

As sens Hotlips and just as tough.

As they have to be in the real world.

Most Surgeons know that Regent Dispo Surgeons' Gloves from LRC are extra tough and yet extra sensitive, with a uniquely roughened surface for extra grip.

And they come in a range of sizes which help make them the best fit around. If fact they are the gloves specially developed for British Surgeons to their specific requirements.

Which makes them all in all a most superior glove, a little like the lady from M.A.S.H.

Quite an operation

When it comes down to it, any operation can only be rated successful if it produces the required result. And tying up the loose ends is important at the end. Thats why Key Med's operation maintains a veritable army of specialists—a skilled task force of experts, disciplined not only to meet the needs of today, but to anticipate and deal with the challenges of the 80's. To ensure that you receive a complete package of products and services, calculated to meet any eventuality.

But we also believe in after-sales service and problem solving. The best briefing in the world can hit snags when practice replaces theory. We are reactors in every sense of the word. And the main link in our chain is to be on-call when required. Which, we're happy to report, isn't often! Key Med is geared up to produce confidence at the outset, and success at completion. A value for money operation you should know more about.

in 1976–7 only 9 per cent were older than 35 years when admitted with ectopic pregnancy.

Only 30 per cent of the primigravid patients were unmarried, compared with the total population, where 50 per cent of all first pregnancies in Aberdeen are conceived out of wedlock. Ten per cent of parous women were unmarried, widowed or divorced.

Past history

Pelvic sepsis: Ten per cent of patients had a history of pelvic inflammatory disease. This is probably a falsely low figure and many women may have had mild disease without being aware of it or were unwilling to confess to venereal disease. Five patients had a history of pelvic tuberculosis.

Previous abdominal operations: Forty-two per cent of all patients had previously undergone some form of abdominal surgery (*Table VI*). There is a high incidence of peritubular adhesions following any abdominal operation, and at the time of surgery for the ectopic pregnancy 25 per cent of all our cases were documented as having pelvic adhesions.

Intrauterine contraceptive device: The overall incidence of IUCD usage in the series was 7 per cent, and in more recent years the incidence rose to 13 per cent. The IUCD was *in situ* when the ectopic pregnancy occurred.

Fertility investigations: Twenty per cent of patients had had fertility investigations under general anaesthesia.

Parity: About 40 per cent of patients had no children who had lived and 25 per cent were primigravid women. Ectopic pregnancy is usually a disease of low parity except in developing countries.

Symptoms

Symptoms commonly recorded are shown in *Table VII*.

Because many patients complain of intermittent vaginal bleeding they are often referred for investigation of dysfunctional uterine haemorrhage. Lower abdominal pain was almost universal and most patients had some form of bleeding. If the patient has no pain at all and no bleeding the diagnosis is unlikely to be ectopic pregnancy.

Other common symptoms were diarrhoea, fainting attacks and dyspareunia.

Table VII: SYMPTOMS

Vaginal bleeding	
Intermittent	50%
Continuous since LMP	20%
Brown discharge only	20%
No bleeding	10%
Abdominal pain	
Sudden onset, severe	47%
Gradual onset, mild	50%
Suprapubic	37%
Right iliac fossa	22%
Left iliac fossa	18%
Generalized	12%
No pain at all	2%

Signs

The most reliable sign is that of cervical excitation (extreme tenderness when the cervix is moved), and this was found in 85 per cent of the patients who had vaginal examinations. Rebound tenderness was also commonly elicited. A pelvic mass was noted in 45 per cent of cases but in many of these the ectopic pregnancy was found to be on the opposite side to that of the supposed mass. Preoperatively the hunt for a pelvic mass is usually unhelpful as well as being potentially dangerous.

Investigations

There is no preoperative test that will definitely identify an ectopic pregnancy. However, a pregnancy test can be useful if it is positive. This was performed in hospital in 40 per cent of cases and found to be negative in one-third of those patients who had ectopic pregnancy. Sometimes a test done earlier by a general practitioner had been positive but had become negative by the time the patient entered hospital. This was particularly useful information.

Haemoglobin: This was estimated on almost every patient but is of little use in the presence of acute bleeding. However, a falling haemoglobin may indicate the presence of chronic bleeding and haematocele.

White cell count and ESR can be useful in identifying pelvic sepsis.

Ultrasound: This has been used in very few of our patients to diagnose ectopic pregnancy, and even when it has been used it has been most unhelpful. Other units have found it a useful diagnostic aid.

Proof puncture: Needle aspiration of the posterior fornix was performed in 17 per cent of our cases but has been used much less in recent years (*Fig.* 3).

Laparoscopy: There has been a marked increase in the use of laparoscopy to diagnose pelvic pain, and 40 per cent of all ectopics in the series had had a laparoscopy just before laparotomy. This investigation is not generally used on those patients admitted to surgical wards and is not used in shocked patients. There has been a decrease in the number of ruptured ectopics over the years which has been coincident with the increased usage of the laparoscope as a diagnostic tool (*Fig.* 4). It would appear that ectopic pregnancy is being diagnosed at an earlier stage.

Laparotomy: Fifty per cent of our patients were diagnosed by laparotomy to have ectopic pregnancy.

Discussion

The diagnosis of ectopic pregnancy is one of the most difficult and important diagnoses in gynaecology. The difficulty is greatest at general practitioner level where the screening of the 'at risk' patient occurs. There is particular difficulty when the symptoms are minimal and mimic many other less dangerous conditions.

Preoperatively there are no other investigations that definitely point to the diagnosis of ectopic pregnancy, so we are dependent on past history and presentation to identify the 'at risk' group of women. The mean age of women with ectopic pregnancy is decreasing and there was a surprising number of teenage girls in our series. This may be due to the fact that more young girls are having intrauterine contraceptive devices inserted as a means of contraception. Most series report the condition in the older age group, except a series from Zambia in which 70 per cent were under the age of 30 (Lucas and Hassim, 1970).

There is a well-established relationship between pelvic sepsis and ectopic pregnancy. In another large series 20–40 per cent had a history of salpingitis and 50 per cent had microscopic evidence of acute or chronic salpingitis at the time of operation (Jarko, 1949; Douglas, 1963). It was surprising in our study, however, that there was not an increasing association between pelvic sepsis and ectopic pregnancy at a time when the incidence of venereal disease is increasing in this community.

Our incidence of 8 per cent of women who had had a previous ectopic pregnancy, although similar to the Jamaican series (Douglas, 1963), is higher than most series. In 10 series with a total of 1300 ectopic pregnancies there was a 5 per cent incidence of previous ectopic pregnancy (Jarko, 1949).

Failed sterilization is becoming an increasing cause of ectopic pregnancy. An analysis of 77 failed sterilizations showed an incidence of ectopic pregnancy of 16 per cent (Hughes, 1977). Our incidence (7 per cent) of women using an intrauterine contraceptive device compares with other series (Lehfeldt et al., 1970), and it is thought that in Britain the recent increase in ectopic pregnancies could be associated with the general increase in the use of intrauterine contraceptive devices (Beral, 1975).

Many of our patients had had investigations for infertility and others had waited many years between pregnancies or before their first pregnancy before having this ectopic. There is a distinctive group of women who have very poor fertility characteristics, and these women have a high risk of an ectopic pregnancy if they become pregnant at all. It has been estimated that patients having infertility investigations have an eightfold increase in the risk of ectopic pregnancy (Wyper, 1962).

The vast majority of our patients gave a history of bleeding or brown discharge. This is not a universal finding and in another series 20–50 per cent of patients did not give a history of any abnormal bleeding or discharge (Lucas and Hassim, 1970) and 50 per cent of patients did not suspect pregnancy (Hallett, 1975). Lower abdominal pain was almost universal in our series. No pain at all in the history is common (ranging from 10 to 20 per cent of patients) in other reported series.

The commonest sign found was cervical excitation and this is in accordance with other series. It does not, however, distinguish between ectopic pregnancy, pelvic sepsis or other pelvic peritonitis.

Proof puncture as a diagnostic tool has little place in the diagnosis of ectopic pregnancy in centres where laparoscopic examination is easily available. Laparotomy alone was performed in all shocked cases and in the vast majority of women admitted to surgical wards. However, in gynaecological wards, diagnostic laparoscopy was almost universal if the diagnosis of ectopic pregnancy was in doubt. With the aid of the laparoscope we are diagnosing ectopic pregnancies earlier now, before they rupture, and only rarely are patients sent home before the diagnosis is made.

The diagnosis of doubtful cases of ectopic pregnancy has been shown to be difficult at all levels of medical practice. The efficiency of diagnosis can be improved if attempts are made to identify high risk groups of patients from their past history, and if laparoscopic examination is freely used in doubtful cases.

Acknowledgements

I am grateful to Dr George P. Milne for encouraging me to undertake this study and to Professor MacGillivray and consultants at Aberdeen Maternity Hospital for their help. I am also grateful to Ms M. Grassick for her usual superb assistance.

The effect of uraemia upon wound healing: an experimental study*

J. F. COLIN, P. ELLIOT AND H. ELLIS†

SUMMARY

Acute uraemia was induced in rats by performing a 70 per cent nephrectomy. Uraemia was shown to delay the healing of intestinal anastomoses and abdominal wounds in rats as judged by bursting strength tests. Cellular proliferation was depressed at wound edges but there was no reduction in the total amount of hydroxyproline present in the wounds. Fibroblast growth in tissue culture was affected by the addition both of uraemic plasma and of urea solution to the culture medium. The possible causes of these effects are discussed.

ACUTE renal failure following severe battle injury was noted during World War I (Minami, 1923), but it was not until the Korean War that surgeons suggested that renal dysfunction may impair wound healing (Balch et al., 1955; Teschan et al., 1955; Bluemle et al., 1959). Some experimental evidence (Nayman, 1966; Mott and Ellis, 1967; McDermott et al., 1968, 1971a, b) has shown that certain aspects of wound healing may be adversely affected by uraemia.

The present study investigates the effect of acute uraemia upon the healing of abdominal incisions and anastomoses of the small intestine in the rat. In addition, some observations are made on the growth of rat skin fibroblasts in media containing uraemic plasma and in media containing urea solution.

Material and methods

Production of a uraemia model

Female Sprague Dawley rats weighing between 250 and 300 g were rendered uraemic by performing a 70 per cent nephrectomy. Under intraperitoneal nembutal anaesthesia, the abdomen was opened and the right kidney removed. The left kidney was separated from its surrounding tissues (leaving it attached medially only by the vascular pedicle and the ureter) and the upper and lower thirds of the kidney were removed using a diathermy needle. Blood was taken on alternate days for estimation of the plasma urea and electrolytes and total protein.

Bursting strength of the abdominal wall

A 5-cm-long midline abdominal incision was made. In the control group of rats a right nephrectomy was then performed; in the uraemic group the animals were made uraemic as described above. The abdominal incision was then closed in a standard fashion, using nine interrupted thread sutures. The rats were killed with ether on the third, fifth or seventh postoperative days and the bursting strength of the abdominal wall measured by a technique previously described from this laboratory (De Hann et al., 1974). This comprised the insertion of a rubber condom into the peritoneal cavity through a defect made in the apex of the vagina. The condom was slowly inflated with oxygen from a cylinder at the rate of 100 ml/min and the point at which the wound dehisced was measured on a mercury manometer. The sutures were removed before this procedure was carried out.

Bursting strength of anastomosis of the small intestine

The ileum was transected 10 cm from the caecum and anastomosed end to end with a continuous everting suture of 6/0 catgut. The rats were killed on the third, fifth or seventh postoperative days. The segment of bowel containing the anastomosis was removed together with any adjacent adherent viscera. One end of the segment of bowel was tied with a piece of thread, the segment immersed in normal saline and the bowel inflated with air from a continuous slow injection pump at the rate of 1·5 ml/min. The bursting pressure was that point at which bubbles of air first left the bowel and were recorded on a mercury manometer.

Hydroxyproline estimations

The hydroxyproline content of tissues was estimated by a modification of the method of Woessner (1961). Using this method the hydroxyproline content of normal rat midline abdominal skin and the hydroxyproline content of standard segments of the midline incision in the control and uraemic rats on the third, fifth and seventh postoperative days were estimated. Similarly, the hydroxyproline content of normal small intestine in control rats and normal small intestine in uraemic rats together with the hydroxyproline content of anastomoses of the small intestine on the third, fifth and seventh days in control and uraemic rats was estimated.

Autoradiographic study of healing abdominal skin wounds

Seven rats, 3 uraemic and 4 controls, were used. Five days after a midline abdominal incision had been sutured the rats were given an intraperitoneal injection of tritiated thymidine, 2 μCi/g of body weight, and were killed with ether 60 min later. A segment of the skin wound from the centre of the incision was removed, fixed in 10 per cent formalin and sections were cut and stained with haematoxylin and eosin. Autoradiographs were prepared by the dipping technique using Ilford Nuclear Research emulsion G5. These were exposed for 3 weeks and subsequently examined under the light microscope. The percentage of labelled fibroblasts and capillary endothelioid cells in the granulation tissue under the epidermis provided an estimate of cellular proliferation. The criterion for labelling was 8 grains/nucleus, which was well above the background grain density.

Using a graticule, all the cells in three fields on either side of the incision, at the wound edge, were counted. Thus six fields were counted in each wound and a minimum of 700 cells were counted in each specimen. The labelling index is the percentage of cells that are labelled in each specimen. Although labelled cells could be seen in the basal cells of the epidermis and in the hair follicles, these were never counted. Neither was any consideration given to the phase of the skin cycle of the adjacent skin.

Fibroblast culture in uraemic rat plasma and urea solution

Small pieces of abdominal skin were removed from female Sprague Dawley rats, stripped of all fat and hair, cut into pieces of approximately 1 mm square and placed in tissue culture Petri dishes. Cover slips were placed on top of the pieces of skin in order to keep them flat on the surface of the Petri dishes and medium TC 199 (Hepes buffer) with heat-inactivated 20 per cent fetal bovine serum (FBS) was added. The Petri dishes were incubated for 5 days at 37 °C until outgrowths of fibroblasts were seen. The fibroblasts were subsequently seeded into Falcon bottles where they were allowed to grow. Viable fibroblasts were taken from the Falcon bottles and seeded in known numbers into Teflon rings which contained medium TC 199 20 per cent FBS, or medium TC 199 20 per cent FBS plus uraemic plasma (urea 66 mmol/l), or medium TC 199 20 per cent FBS plus pure urea solution (66 mmol/l). After 48 h the fibroblasts were examined under the light microscope and the condition and the shape of the cells and the type of cell growth recorded.

In a second group of experiments, microsyringes were used to seed 6000 fibroblasts of approximately 99 per cent viability into the microcytotoxicity plates. One group of microcytotoxicity plates contained fibroblasts in medium TC 199 plus 20 per cent FBS only. In a second group the fibroblasts were cultured in the same medium plus additional uraemic plasma. The plasma contained differing amounts of urea, namely 66 mmol/l, 22 mmol/l, 15 mmol/l and 8 mmol/l. In a third group fibroblasts were grown in medium TC 199 20 per cent FBS plus pure urea solution. Again the urea solution contained different amounts of urea, namely 66 mmol/l, 22 mmol/l, 15 mmol/l and 8 mmol/l respectively.

The plates were incubated for 24 h after which they were examined for general growth, numbers and shape, using phase contrast microscopy.

Results

The method used to produce uraemia caused a significant ($P<0.00001$) elevation of the blood urea level which lasted over a period of 7 days. The mortality was 10 per cent (*Fig.* 1).

The observed levels of blood urea in both the control and uraemic rats were not normally distributed (Kolmogorov–Smirnov test for goodness of fit: Kolmogorov, 1941; Smirnov, 1948). For this reason the Mann–Whitney (1947) test was used to analyse the data. As there was an *a priori* assumption that the bursting strength in uraemic rats was less than in controls, one-tailed probability values are given in the results. The null hypothesis was that there was no significant difference between controls and uraemics. A significant difference was defined as $P<0.01$.

Tests of bursting strength

Abdominal incisions: The bursting strength in the control animals was significantly higher than that in the uraemic animals on the third, fifth and seventh postoperative days ($P = 0{\cdot}01$ 3 days, $P < 0{\cdot}01$ 5 days, $P < 0{\cdot}0005$ 7 days) (*Table I, Fig.* 2).

Intestinal anastomoses: The bursting strength of normal small intestine was the same in control and uraemic animals (*Table I, Fig.* 3).

The bursting strength of anastomoses of the small intestine was greater in control rats than in uraemic rats on the third, fifth and seventh postoperative days ($P < 0{\cdot}025$ 3 days, $P < 0{\cdot}0025$ 5 days, $P < 0{\cdot}001$ 7 days).

Hydroxyproline measurements

Skin wounds: There was no difference in the amount of hydroxyproline present in the abdominal skin wound in the control or uraemic rats on the third and seventh postoperative days (*Table II, Fig.* 4). On the fifth postoperative day the uraemic group contained more hydroxyproline than the control group ($P < 0{\cdot}0045$).

Intestinal anastomoses: Unwounded small bowel of control and uraemic rats contained the same amount of hydroxyproline (*Table II, Fig.* 5).

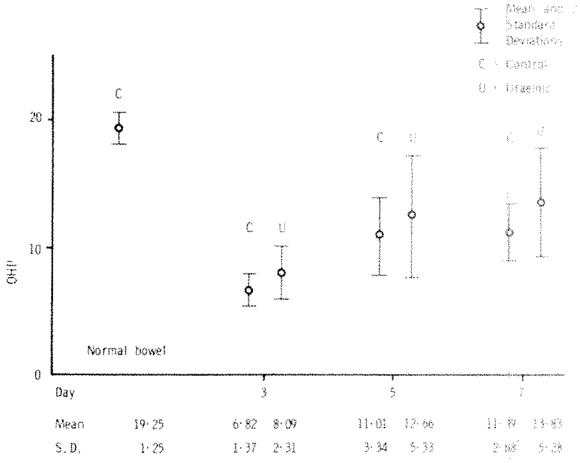

Fig. 5. Hydroxyproline content (mg/g dry tissue) of small bowel anastomoses on days 3, 5 and 7 in control and uraemic rats.

There was no difference between the amount of hydroxyproline present in the anastomoses of the small intestine in the control and uraemic group on the third, fifth and seventh postoperative days. In addition, a non-parametric regression of hydroxyproline levels, in both skin wounds and anastomoses, against blood urea levels showed no association ($r = -0{\cdot}07$).

Autoradiographic study (*Table III*)

The granulation tissue of the wounds in the control and uraemic groups contained labelled fibroblasts, endothelioid cells and mononuclear cells. However, the number of labelled cells was fewer in the uraemic

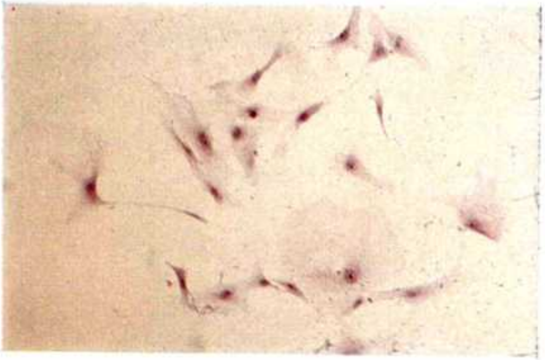

Fig. 6. Normal fibroblasts grown in culture. (× 800.)

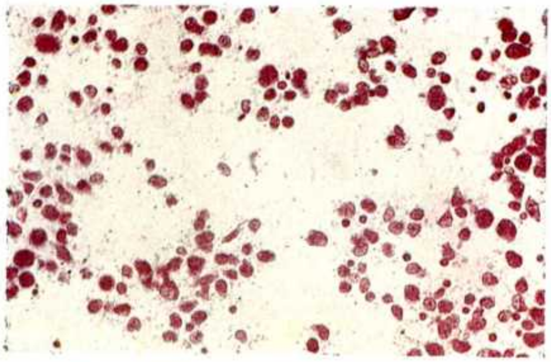

Fig. 7. Abnormal fibroblasts grown in culture to which uraemic plasma has been added. (× 800.)

group than in the controls. In one specimen with a blood urea level of 7 mmol/l, the labelling index was 13·9 per cent whilst in another specimen in which the blood urea was 31 mmol/l the labelling index was only 3·2 per cent.

Fibroblast culture

Fibroblasts grown from rat skin in culture medium TC 199 20 per cent FBS grew well, were typical in appearance and the viability of the cells was good (*Fig.* 6). When uraemic plasma was added to the medium, the subsequent behaviour of fibroblasts varied with the amount of urea in the plasma. In media containing urea 22 mmol/l or 66 mmol/l, although the cells were viable, they were all rounded in appearance and did not grow profusely (*Fig.* 7). If the media contained plasma with 15 mmol/l urea, most of the fibroblasts were normal in shape, though some were rounded, but they were all viable. In the media containing plasma with 8 mmol/l urea the growth of fibroblasts was normal, their shape and number were normal and the viability of the cells was good.

The addition of pure urea solution had a profound, and much more marked, effect on the growth of fibroblasts. When urea 66 mol/l was added to the medium, many (average 61 per cent) of the cells died and the remainder were rounded in appearance. With the addition of urea 22 mmol/l to the media, about half (average 46 per cent) of the cells died and the remainder were rounded in shape. If the media contained urea 5 mmol/l most of the cells were alive but rounded in shape and the growth only half as good as in the normal media without the addition of urea solution. In media containing urea solution 8 mmol/l, some of the cells were typical fibroblasts, although most were rounded in appearance. The viability of the cells was good, however, although the growth was only two-thirds of normal.

Discussion

Our studies have shown that acute uraemia in the rat is associated with a lowering of the bursting pressure of midline abdominal incisions and of anastomoses of the small intestine up to the seventh postoperative day. In addition, we have shown that there is a decreased rate of cellular proliferation at the healing wound edge, but no reduction in the total amount of hydroxyproline present in the wound. Our tissue culture studies have shown that fibroblasts grown in media containing uraemic plasma do not have a normal form. However, the effect of the addition of uraemic plasma is not so deleterious as is the addition of equivalent amounts of pure urea solution.

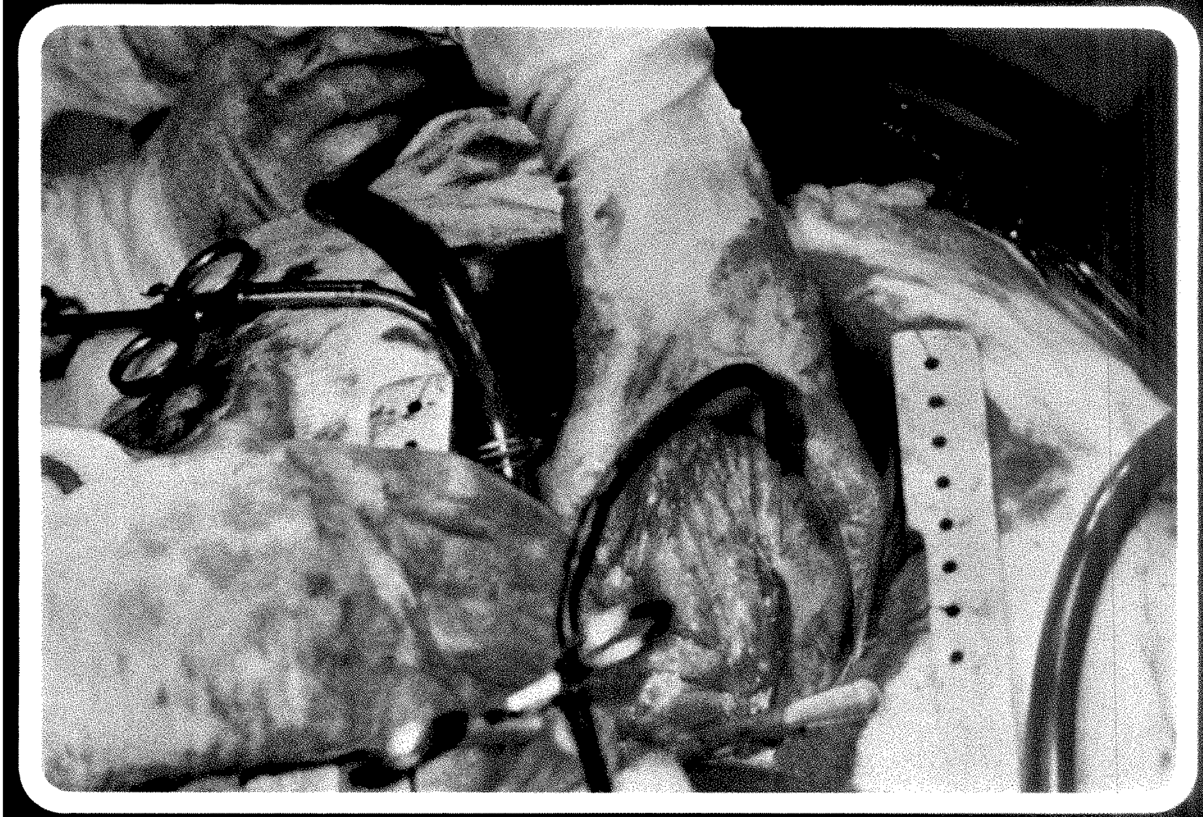
Changes in the concentration of salts and amino acids in a tissue culture medium can result in morphological changes in the cultured cells. However, growth inhibition and killing of cells are not observed (Paul, 1970), but these did occur with the addition of urea or uraemic plasma to the tissue culture medium.

A depressed rate of granulation tissue formation in healing wounds in uraemic mice has previously been reported (McDermott et al., 1968) and epithelial cell division in the mouse jejunum, oesophagus and stomach has also been shown to be depressed in uraemia (McDermott et al., 1971a, b; Castrup et al., 1972). It has also been shown that the healing of peritoneal defects in uraemic rabbits is delayed and collagen fibre formation, in the depth of the defects, lags behind that of controls (Mott and Ellis, 1967). Uraemic serum has been shown to have cytotoxic effects in other spheres (Arpels and Southam, 1969; McDermott, 1971), and acute renal failure has been shown to have an inhibitory effect on cell division in lymphoid tissue (Burwell et al., 1962; Silk, 1967).

Our studies on the total hydroxyproline content of the healing wounds showed that there was no difference between the controls and the uraemic rats except in one instance. This was on the fifth postoperative day at which time the hydroxyproline content of the abdominal skin wound was found to be higher in the uraemic group than in the control group. Clearly, the decrease in the bursting strength of the abdominal incisions and the anastomoses in the uraemic rats was not accompanied by a decrease in the total hydroxyproline content of the wound. However, the method used for harvesting the tissues for hydroxyproline estimation in this study could have resulted in small differences in the hydroxyproline values not being recorded. The estimation of the total hydroxyproline content of the healing wound does not differentiate between the new collagen that has been formed and the old collagen that has been broken down. The decrease in the bursting strength in the uraemic group without a change in hydroxyproline content could be explained by the production of a collagen of poor quality, as occurs in lathyrism, or by an increased destruction of old collagen, affecting the strength of the wound without changing the total hydroxyproline content. Clearly further studies using tritiated proline as an isotope label to determine the rate of new collagen production

Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

rescribing Information

lagnapen Capsules: Black and turquoise capsules verprinted 'Magnapen' containing 250mg ampicillin as mpicillin Trihydrate B.P. with 250mg flucloxacillin as ucloxacillin sodium.

lagnapen Syrup: Bottles containing powder for the reparation of 100ml suspension. When reconstituted each ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. ith 125mg flucloxacillin as flucloxacillin sodium.

lagnapen Vials: Each vial contains 250mg ampicillin as mpicillin Sodium B.P. with 250mg flucloxacillin as ucloxacillin sodium.

ses: Severe infections. Post-operative chest and wound

Dosage: Adult 1 capsule or 10ml syrup, or 1 vial qid. Children 2-10 years ½ adult dose. Under 2 years ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL 0038/5001, 5009

Contra-indications: Penicillin hypersensitivity, ocular administration.

Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.

Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product

Basic N.H.S. Prices: (correct at time of printing) [illegible]
Capsules 500mg £18.06 (100) [illegible]
Syrup 250mg per 5ml £3.18 (100ml)
Vials 500mg £7.45 (10 vials)

Magnapen is available to hospitals [illegible] dependent upon estimated usage.

Further information on Magnapen is available on request to the company.

Bayer BAYER

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*

(Cronin et al., 1968; Madden and Smith, 1970) would be of interest.

In uraemia enzyme systems, biochemical pathways and cellular metabolism are altered (Hollunger, 1955; Galloway and Morgan, 1964). The levels of free and bound hydroxyproline in the plasma are raised in uraemia due to the impairment of the hepatic enzyme, hydroxyproline oxidase (Avioli et al., 1969), so it would not be surprising if the synthesis of new collagen or the degradation of old collagen in healing wounds was altered in uraemia.

Circulatory inhibitors to skin collagenases have been demonstrated in human serum (Eisen et al., 1970) and Hawley and Page Faulk (1970) have identified an alpha-globulin in the sera of rabbits which inhibits the action of collagenase from the rabbit colon. Following injury the amount of circulatory inhibitor decreases. Alterations in the fractions of the plasma proteins in uraemia are known to occur. Amino acid metabolism and protein synthesis are altered (Shear, 1969) and antibody production is decreased (Souhami, 1971). In humans with uraemia increased levels of an alpha-2-globulin have been found in the serum (Finkle et al., 1956). It could be that in uraemia there are alterations in the amount of circulatory collagenase inhibitors, so that lysis exceeds synthesis, thus lowering the strength of wounds.

Protein deficiency or anaemia was not responsible for the observed changes in the bursting strengths in the uraemic group as there were no changes in these factors when compared with the controls. Although the uraemic rats may have been dehydrated, there were no changes in the plasma sodium levels when compared with the controls, so this is unlikely to have been an important factor. The uraemic rats all lost more weight than the controls so that by the seventh day they had lost on average 10 per cent of their initial body weight. However, Irvin and Hunt (1974) showed that malnutrition impaired colonic healing in rats only if over 34 per cent of the body weight had been lost.

This study has clearly shown that acute uraemia in rats delays the early phase of wound healing and severely affects cellular proliferation in the wound and fibroblast growth in tissue culture media. The most likely explanation is that the uraemic state causes this effect by altering some processes of cellular metabolism.

The presentation of gastrointestinal lymphoma: study of a population

JOHN A. GREEN, AUDREY A. DAWSON, PETER F. JONES
AND PETER W. BRUNT*

SUMMARY

The clinical presentation and findings in 45 patients with lymphoma of the gastrointestinal tract occurring in an unselected population are described. Nineteen patients presented as emergencies with haemorrhage, perforation, pyloric stenosis or intestinal obstruction. Systemic symptoms, peripheral lymph node enlargement and hepatosplenomegaly were rare, and a preoperative diagnosis of lymphoma was seldom made. Endoscopy was superior to radiology in defining lesions in the stomach and duodenum. Lesions which were multicentric, or of unusual macroscopic appearance, were common in the small bowel, and these should raise the suspicion of lymphoma.

Local and systemic recurrence was common, but was not always fatal. Patients with gastric lymphomas survived longer than those with intestinal disease.

THE organization of medical services in North-East Scotland (Grampian Region) provides a unique opportunity for unselected epidemiological study. The area is well defined, with a population of 475 000, and all patients with major disease are referred to the Aberdeen Teaching Hospitals. In this population a study has been made of both planned and emergency admissions of patients found to have gastrointestinal lymphomas over the 6 years 1972–7. Gastrointestinal lymphoma is considered to be a rare disease in adults in Great Britain, but 45 cases were traced in 6 years, 19 presenting as emergencies. Previous British (Azzopardi and Menzies, 1960; Dawson et al., 1961) and North American (Joseph and Lattes, 1966; Bush and Ash, 1969; Loehr et al., 1969; Hertzer and Hoerr, 1976; Lewin et al., 1978) reviews have come from specialist or referral centres, which may see relatively few emergency cases. The objective of this paper is to show the ways in which this condition presents, and to highlight the difficulties in reaching a definitive diagnosis before and during surgery.

Patients and methods

The Aberdeen Hospitals serve the population of the Grampian Area, and inhabitants of the Orkney and Shetland Islands with major disease also come to Aberdeen. The records of patients from these areas with proved gastrointestinal lymphoma were obtained. The files of the Department of Pathology, University of Aberdeen (which examines biopsy material from the whole area), and of the Information Unit of the Grampian Area Health Board have also been searched.

A total of 291 cases of non-Hodgkin's lymphoma was seen during 1972–7; there were 45 patients in whom lymphomatous involvement of the stomach or intestine was the principal site of disease. Mesenteric involvement alone did not justify inclusion. In 40 patients the gastrointestinal tumour was the only clinical evidence of disease. In a further 5 patients coexisting evidence of lymphoma at other sites (in neck nodes, thyroid, testis and chest wall) was present, but involvement of the gastrointestinal tract was clearly the predominant disease in each instance. There was histological confirmation of gastrointestinal involvement in 42 cases. In the other 3 patients, who had histologically proved lymphoma at another site, there was radiological and endoscopic evidence of involvement of the stomach, duodenum and ileum.

Staging was usually carried out postoperatively, according to the Ann Arbor classification (Carbone et al., 1971), and by definition all had extranodal disease denoted by the suffix 'E'. Patients who recovered from surgery and were adequately staged were treated with wide-field abdominal radiotherapy if there was known or probable local residual disease. Patients with localized disease in whom surgical removal was considered complete were, during the earlier period of the study, observed and appropriate treatment with either chemotherapy or radiotherapy begun at any sign of further disease; in the later stages of this series, such patients were treated immediately with adjuvant chemotherapy in view of the high recurrence rate found in earlier patients. Patients with evidence of extra-abdominal disease (most often mediastinal node involvement) were treated with chemotherapy, using cyclophosphamide, doxorubicin, vincristine and prednisolone intermittently, sometimes after abdominal radiotherapy.

The length of survival and the time to first clinical evidence of recurrence were noted.

Results

Table I shows the distribution of the series according to site of tumour, patient's age and clinical stage. There were 25 males and 20 females. Four patients, 2 with gastric and 2 with small bowel disease, were under the age of 30, while half the patients were over the age of 65 at the time of diagnosis. Where multifocal tumours were present, they were in the same organ, except in 2 cases with small bowel lymphoma, where a second tumour was present in the large intestine. Tumours ranged in size from 1·5 to 30 cm in maximum dimension, with a mean of 6 cm. Thirty-eight cases were regarded as stage IE or IIE, only 7 being more generalized. Enlarged mesenteric nodes were seen and biopsied in 21 cases at laparotomy, but found to be histologically involved in only 11, the remainder showing reactive changes. In 2 cases small involved nodes were found by the pathologist.

Nineteen patients (40 per cent) presented as surgical emergencies (*Table II*). Symptoms of weight loss (7 cases) and abdominal pain (7 cases) preceded the acute episode by 1–12 months (mean 4 months) in the patients with gastric lymphoma. In those with small and large bowel tumours, patients presenting with perforation admitted to no prior symptoms, but those with obstruction frequently had had symptoms, often intermittent, for from 1 week to 6 months before hospital admission.

Among the non-emergency patients symptoms suggested abdominal malignant disease (*Table III*). The mean duration of symptoms was 7 months for gastric lesions (range 2–36 months) and 6 months for intestinal lesions (range 2–16 months). The other clinical features are shown in *Table III.*

Gastric lymphomas

Sixteen of the 22 patients were male. Five had had radiologically proved peptic ulceration in the past (3 duodenal and 2 gastric ulcers) and a further 4 gave a history of typical ulcer pain over periods of more than 5 years. A barium meal was performed in 19 cases, suggesting malignancy in 11, a benign gastric ulcer in 4 and failing to detect any gastric lesion in 4. Endoscopy was performed in 12 patients, and the appearances were suspicious of malignancy in 9. A biopsy was obtained in 11 cases; it confirmed malignancy in 3 cases and suggested lymphoma in 1 of these. In another case, thought to be benign at gastroscopy, histological examination of the biopsy specimen was suggestive of malignancy. Altogether, 14 patients were considered preoperatively to have a malignant gastric ulcer. All 21 patients operated on were recognized by the surgeon to have malignant disease but no lesion was suspected of being a lymphoma, although in 2 patients the appearances were noted to be unusual; one had an ulcer with rolled edges but without the infiltration of a carcinoma, the other showed diffuse plaque-like thickening of the gastric wall.

Small bowel lymphoma: Of the 15 cases, there were 2 proved and 1 possible case of antecedent coeliac disease, while one other patient had evidence of malabsorption. In 8 cases where barium meal and follow-through was performed, mucosal infiltration was suggested in 3, extrinsic jejunal compression noted in 2 and a non-specific abnormality of the terminal ileum in 1. Thirteen patients underwent an operation, 9 as emergencies (6 for perforation with peritonitis, 1 for small bowel obstruction, 1 for a possible twisted ovarian cyst and 1 for appendicular abscess).

The common operative finding was of a length of pale thickened intestine, often associated with considerable mesenteric thickening and lymph node involvement. When perforation had occurred, the opened specimen showed the perforation to be at the centre of a penetrating mucosal ulcer. In 2 cases the mural thickening had produced occlusion of the

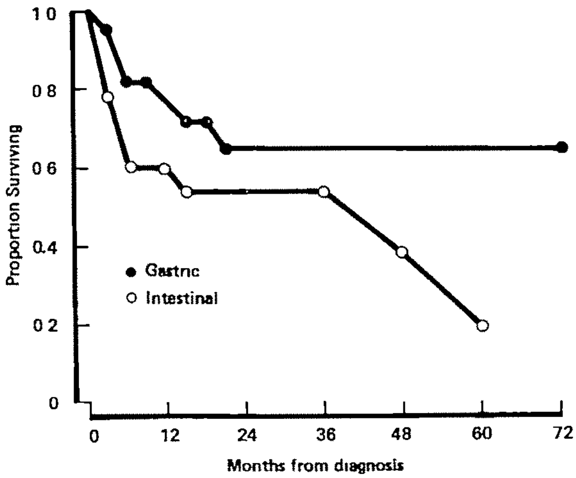

Fig. 1. Life table analysis of survival in 45 cases of gastric and intestinal lymphoma.

lumen and 1 of these patients had a perforation above the obstruction.

Large bowel lymphoma: Of the 8 patients, 2 presented with rectal bleeding, 1 with obstruction and the others with vague abdominal pain, diarrhoea and weight loss. Localized perforations were found in 2 cases. Barium enema examination was performed in 6 cases and the radiologist suggested malignancy in 3 cases of caecal lymphoma and diagnosed malignant stricture in one colonic lymphoma and Crohn's disease in another; the enema failed to demonstrate any abnormality in 1 patient. The findings both at presentation and at operation were indistinguishable from colorectal carcinoma.

Of all 45 cases, the presence of lymphoma was suspected prior to laparotomy in only 7, of whom 5 had coexisting lymphoma at other sites. Gallium-67 scan showed increased abdominal uptake in all 7 patients in whom it was performed. Of the remaining 38 cases, the preoperative diagnosis was suspected malignant tumour in 25.

Operation was performed in 41 patients and removal was regarded as complete in 28 of these. Clinical staging, including scans and bone trephine biopsy, was carried out in all patients fit for further treatment. Eleven patients were treated with wide-field abdominal telecobalt therapy, 6 immediately after operation and 5 later for recurrence. Twenty-two patients had cytotoxic chemotherapy (normally cyclophosphamide, doxorubicin, vincristine and prednisolone), 16 postoperatively and 6 later for recurrence.

There were 14 recurrences, purely local in 7, at a mean of 11 months after diagnosis of the first lesion (*Table IV*). Recurrence was not always fatal and 4 patients were alive more than 30 months later. One patient subsequently developed a perforated duodenal ulcer, another an ileal perforation; both sites were histologically free from tumour and abdominal irradiation had not been given. Nineteen patients have died, 14 within 6 months of diagnosis. Four of these died postoperatively of pulmonary embolism or infection—2 being patients presenting with perforation. Two patients suffered fatal septicaemia while having chemotherapy. The mean survival of those who died was 7 months compared with 30 months for those patients still alive at follow-up. The mean age at presentation of those who died was 63 years compared with 57 years for the survivors. The gastric lymphoma patients were younger (*Table I*), there were fewer deaths among them in the observation period and they survived longer (mean 43·1 months compared with 27·6 months) than the patients with intestinal lymphoma. Life table analysis suggests a better prognosis for the gastric lymphomas and demonstrates that the majority of deaths in the whole group occurred early (*Fig.* 1).

Five of the 6 patients treated by surgery and radiotherapy at diagnosis are still alive; 9 of the 16 treated by surgery and immediate chemotherapy are alive at 12–23 months after diagnosis, 7 having died at 1–15 months; 10 of the 17 treated by surgery alone are still alive 3 years or more after diagnosis.

Discussion

This series is unique in the literature in being a study of all the gastrointestinal lymphomas diagnosed in a defined population over 6 years. The high proportion of elderly patients largely explains the high short term mortality. The disease was much more frequently localized to the gastrointestinal tract than in the large series of non-Hodgkin's lymphomas of Jones and his colleagues (1973), where only 30 per cent of gastrointestinal cases were staged as IE, IIE and IIIE, but previous smaller surgical series showed localized disease to be common (Azzopardi and Menzies, 1960; Naqvi et al., 1969). In these latter series from specialist centres a considerable element of selection was present.

The high incidence of emergency presentation of gut lymphomas, their large size and the difficulty in their radiological diagnosis have been noted previously (Dawson et al., 1961; Joseph and Lattes, 1966). These findings are explained by the lateral spread of lymphoma within the submucosal plane, sparing the muscular coat until late in the disease, in contrast to carcinoma.

Gastric lymphoma represents only 1–2 per cent of malignant gastric tumours. The tumour mimics benign or malignant ulceration. In our hands, endoscopy proved a more useful investigation than radiology. It is difficult to distinguish gastric lymphoma from carcinoma at operation. The male predominance in the gastric lymphomas has been noted by others (Loehr et al., 1969; Hertzer and Hoerr, 1976).

Prodromal symptoms are relatively uncommon in small bowel lymphoma. A small proportion may present with malabsorption (Isaacson and Wright, 1978), of whom some will have adult or lifelong coeliac disease (Harris et al., 1967; Brunt et al., 1969). In our series, only 2 were thought to have this association. A striking feature was the high incidence of perforation, as noted by others (Irvine and Johnstone, 1955). In this respect, small bowel lymphoma contrasts with Crohn's disease, with which confusion is common, and in which perforation is relatively rare. Differentiation from Crohn's disease is often difficult, especially when the lymphoma causes mesenteric thickening and node enlargement at the terminal ileum, but distinction is therapeutically very important. Further diagnostic difficulty occurs in distinguishing small bowel lymphoma from carcinoma and carcinoid, though lymphomas often involve longer segments and are frequently multiple. One technique for attempting rapid differentiation of lymphoma from carcinoma at operation is that of imprinting of the opened tumour on glass slides, stained by Romanowsky stains. We have found this reliable in the few cases studied and we hope to test this method further.

Preoperative diagnosis of gastrointestinal lymphoma, even in non-emergency cases, was rare in our experience. However, there was a suspicion of malignant disease in most patients and this meant that major elective surgery was undertaken. Complete surgical excision offers the best chance of long-term disease-free survival (Peckham and McElwain, 1977). Resection was usually feasible although it did involve considerable technical difficulties in dealing safely with thickened intestinal mesentery. When the diagnosis of lymphoma is suspected at operation, full pathological staging, including liver and node biopsy, should be carried out if at all possible. This avoids the need for a 'second look' laparotomy, which is often impossible in an elderly, debilitated patient.

The operative mortality of 9 per cent compared favourably with that in the earlier series of Navqi et al. (1969), who quoted a figure of 19 per cent: however, most of those deaths occurred before 1950. Recurrence was commoner in those with small bowel tumours and in those with tumours originally noted to be multifocal, but recurrence was not invariably fatal, as has been suggested by Bush (1974). Gastric lymphomas had a better prognosis than those in the intestine.

In a small series, with a short follow-up period, it is not possible to draw firm conclusions on the results of treatment. There is certainly a group of patients whose tumours affect all parts of the gut, who do badly irrespective of the type of treatment and who die within 18 months. Our figures show that some patients do very well with surgery alone, or with postoperative radiotherapy alone, but these are probably favourable cases from the start. In the planning of rational treatment it is vital to have adequate biopsy material. It is therefore important for the surgeon to keep the possibility of lymphoma in mind. In suspicious circumstances it is easy to obtain biopsies of liver and lymph nodes and these can be of great value in planning treatment.

Acknowledgements

We wish to thank the several clinicians of the Aberdeen Teaching Hospitals who referred patients to us for further study and treatment, and Dr G. Innes, Reader in Community Medicine, University of Aberdeen, for the valuable help of the Information Unit.

Pneumatosis coli and sigmoid volvulus: a report of 4 cases

J. GILLON, S. HOLT AND W. SIRCUS*

SUMMARY

Pneumatosis coli is an uncommon disease which is frequently misdiagnosed and inappropriately treated. The condition can usually be managed conservatively but complications requiring surgical treatment are occasionally encountered. We describe 4 patients with pneumatosis coli and associated volvulus of the sigmoid colon. Some of the factors that may have contributed to pneumocyst formation in these 4 patients are discussed with reference to recent advances in our understanding of the pathogenesis of pneumatosis coli.

PNEUMATOSIS coli is an uncommon disease of unknown aetiology in which multiple gas-filled cysts are encountered within the wall or mesentery of the large bowel. In a review of the literature, Koss (1952) found that only 47 of the 213 reported cases of pneumatosis cystoides intestinalis (PCI) had lesions in the colon, and in only 13 of these were pneumocysts restricted to the large bowel alone. More recently a change in the overall pattern of the disease appears to have occurred, with a predilection for the gas cysts to affect the left hemicolon, without small intestinal involvement (Wyatt, 1975).

Pneumatosis coli most commonly occurs as a primary idiopathic disorder, but a secondary form of the disease has been described in association with a variety of conditions including obstructing and ulcerative lesions of the colon, inflammatory bowel disease and after trauma (Wertkin et al., 1976). There are a number of reports which document the resolution of secondary pneumatosis coli with adequate treatment of the associated gastrointestinal lesion (Wyatt, 1975), and high flow oxygen therapy has provided a safe form of treatment for patients with symptomatic pneumatosis coli whether primary or secondary (Forgacs et al., 1973; Down and Castleden, 1975; Holt and Heading, 1978). Surgery is thus only indicated in the event of complications such as volvulus, intestinal obstruction or severe rectal bleeding (Broecker and Moore, 1977; Thomson et al., 1977).

We describe 4 patients in whom pneumatosis coli was associated with a twisted segment of the large bowel and discuss possible aetiological mechanisms.

Case reports

Case 1: A 38-year-old woman presented with a 10-month history of diarrhoea, lower abdominal pain, mucus discharge and slight intermittent rectal bleeding. A clinical diagnosis of ulcerative colitis was made and treatment commenced with oral sulphasalazine. Subsequent barium enema, sigmoidoscopy and biopsy demonstrated typical changes of pneumatosis coli without evidence of ulcerative colitis. The patient was referred to the gastrointestinal unit for further treatment and assessment. On admission to hospital clinical examination was normal. Colonoscopy revealed clusters of gas-filled cysts commencing 18 cm from the anus. A 5-day course of intermittent high flow oxygen therapy using a modification of the method of Down and Castleden (1975) produced a remission of symptoms. Colonoscopy demonstrated a considerable reduction in the number of gas cysts, without complete resolution.

Six months later, diarrhoea and mucus discharge recurred in association with intermittent cramp-like lower abdominal pain. A double contrast barium enema at this stage demonstrated typical changes of pneumatosis coli restricted to a redundant loop of sigmoid colon (*Fig.* 1). Repeat sigmoidoscopy and biopsy confirmed the presence of pneumatosis coli. Oral ampicillin was given (250 mg four times daily) for 2 weeks (Holt et al., 1978), but a subsequent double contrast barium enema examination showed no change.

At laparotomy a very long pelvic loop of colon was found with mesenteric striation suggesting previous torsion. There were numerous subserosal and submucosal gas cysts within the loop, which tapered to normal bowel at both ends. The diseased segment of bowel was resected (*Fig.* 2) and the patient made a good postoperative recovery. She remains well 9 months after operation.

Case 2: A 72-year-old woman was referred in November 1978 with a 7-week history of lower abdominal pain relieved by defaecation. She complained also of occasional diarrhoea, tenesmus, rectal bleeding and mucus discharge and she had noticed intermittent abdominal distension.

In 1967 a barium enema examination performed because of constipation had been found to be normal. A diagnosis of endogenous depression was made. The patient developed diarrhoea with blood and mucus in 1974 but a barium enema was negative.

On this occasion examination was normal apart from generalized gaseous distension of the abdomen. Sigmoidoscopy revealed 'polypoid structures' thought to be a probable carcinoma, but the histopathology was typical of pneumatosis coli. Barium enema demonstrated a redundant sigmoid colon in a position of potential volvulus and containing numerous gas cysts. The lower descending colon appeared normal but there was an area of pneumatosis distal to the splenic flexure.

At laparotomy a redundant sigmoid and descending colon was found containing numerous gas cysts. The mesentery was scarred, suggesting previous torsion. A left hemicolectomy was performed and the patient made an uneventful recovery.

Case 3: A 79-year-old woman was admitted to hospital with a 1-week history of abdominal distension and constipation. Two years earlier she had been admitted with similar symptoms which were related to sigmoid volvulus, confirmed by plain abdominal X-rays, and sigmoidoscopic reduction of the volvulus had been achieved. Clinical examination at the time had revealed gross gaseous abdominal distension; digital examination of the rectum had been normal.

A plain abdominal X-ray at the present admission indicated a volvulus of the sigmoid colon, which was confirmed at laparotomy. At operation a twisted and enormously dilated loop of pelvic colon was noted to be studded with numerous gas cysts typical of pneumatosis coli. The remainder of the large bowel was normal. After decompression of the pelvic colon, a Paul Mikulicz resection was performed. Pathological examination of the resected loop demonstrated typical macroscopic and microscopic features of pneumatosis coli. The patient died suddenly on the seventh postoperative day from myocardial infarction.

Case 4: An 80-year-old woman was admitted with a 3-week history of rectal bleeding and mucus discharge. Four years earlier a cerebral thrombosis had resulted in right hemiplegia.

Correspondence to: J. Gillon.

In the week prior to admission she had had absolute constipation with abdominal pain and intermittent vomiting. Examination revealed advanced congestive cardiac failure, abdominal distension and a large mass in the left hypochondrium. Plain abdominal X-rays showed dilated bowel in the left hypochondrium, which was considered to represent a sigmoid volvulus. The patient was unfit for operation and her condition deteriorated, culminating in her death 3 days after admission. Post-mortem examination revealed rheumatic valvular heart disease affecting the mitral and aortic valves with evidence of gross cardiac failure. The sigmoid colon was obstructed by a 20-cm length of bowel affected by pneumatosis coli. Histology of the affected segment of bowel demonstrated cystic spaces lined by flattened cuboidal cells and occasional giant cells, consistent with pneumatosis coli.

Discussion

The aetiology of pneumatosis cystoides intestinalis has been debated for many years. A number of hypotheses have been put forward to explain the pathogenesis of the condition in humans, these theories often being derived from the known association of PCI with various disease states. Koss, in his major review (1952), drew attention to the then common association with peptic ulceration and pyloric stenosis, and concluded that a mucosal breach could allow gas under pressure to be forced into the submucosal tissues, thereby creating gas cysts. The observation of an association between PCI and chronic obstructive airways disease (Doub and Shea, 1960) led to the suggestion that, following alveolar rupture, air might dissect from the thorax, travel along the adventitia of the great vessels and hence to the mesentery and wall of the bowel. This theory received some support from experimental work in dogs (Keyting et al., 1961), but both these hypotheses fail to take account of the absence of these associated conditions in a large proportion of patients, nor do they explain the primary form of the disease.

Earlier workers have favoured a bacterial causation (Naeslund, 1924; Nitch, 1924; Berglund, 1939), and Nitch described a similar condition affecting swine in epidemic form in summer. The presence in the cysts of hydrogen, an element produced in the body only by bacterial metabolism, provided further evidence that bacteria were involved. We have recently demonstrated a specific abnormality of breath hydrogen excretion in patients with PCI (Gillon et al., 1979), implying constant abnormal gas production by bacteria and providing evidence that this may be a major aetiological factor in the production and maintenance of gas cysts. The bacterial theory has also been supported recently by the experimental induction of pneumatosis in rats using various species of clostridia (Yale and Balish, 1976) and by the observation of resolution of the disease following antibiotic treatment (Wandtke et al., 1977; Holt et al., 1978). Furthermore, quantitative and qualitative bacteriological studies of the cyst walls and colonic mucosa in patients with pneumatosis coli, both before and after oxygen therapy, have revealed the presence of anaerobic organisms which may be present in the normal colonic flora (Holt and Heading, 1978).

The 4 patients described here demonstrate that volvulus of the sigmoid colon may complicate pneumatosis coli and only three separate reports of this association have been documented since the account by Koss (1952) (Frimann-Dahl, 1974; Shallal et al., 1974; Wertkin et al., 1976). The coexistence of sigmoid volvulus and pneumatosis coli is therefore rare. However, a similar situation has been observed in patients who have undergone jejunoileal bypass for morbid obesity (Martyak and Curtis, 1976;

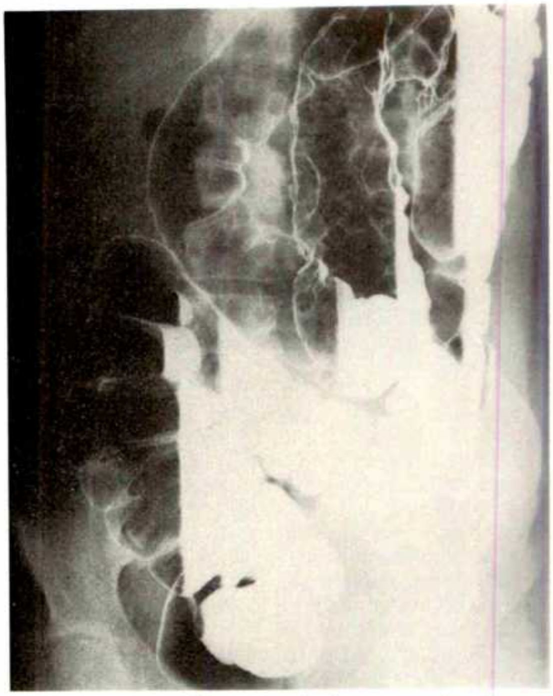

Fig. 1. *Case* 1. Double contrast barium enema showing gas cysts confined to redundant loop of sigmoid colon.

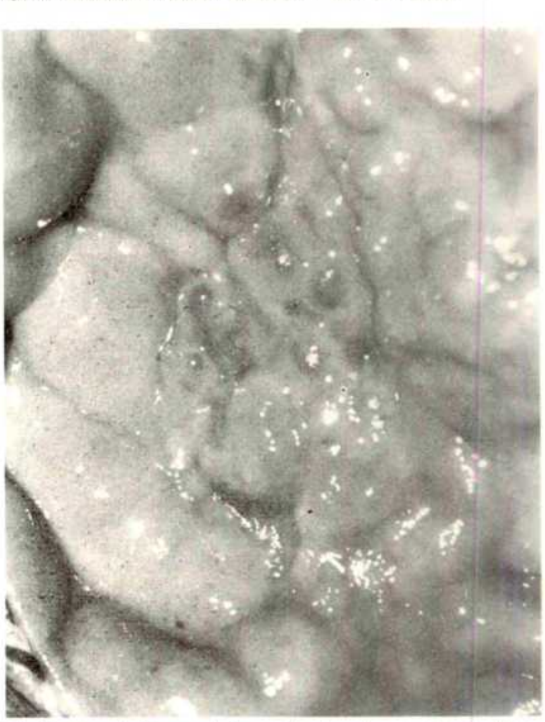

Fig. 2. *Case* 1. Resected sigmoid colon showing typical gas cysts with pneumatosis coli.

Table I: DETAILS OF 4 PATIENTS WITH SIGMOID VOLVULUS AND PNEUMATOSIS COLI

Case	Age (yr)	Sex	History of preceding pneumatosis	Diagnostic investigations	Misdiagnosis	Outcome
1	38	F	16 mth	Barium enema, colonoscopy and biopsy	Yes (ulcerative colitis)	Sigmoid resection. Full recovery
2	72	F	No	Barium enema, sigmoidoscopy and biopsy	Yes (carcinoma)	Left hemicolectomy. Full recovery
3	79	F	No	Plain film of abdomen (laparotomy)	No	Sigmoid resection. Post-operative death
4	80	F	No	Plain film of abdomen (post-mortem diagnosis of pneumatosis)	No	Died

Menguy, 1976; Passaro et al., 1976). In these patients volvulus and partial obstruction occurred at the insertion of the distal end of the bypassed small intestine into the pelvic colon and cystic pneumatosis appeared to be confined to this bypassed loop. The authors proposed that the cysts were caused by gas under pressure within the obstructed loop being forced through the mucosal breach at the anastomotic line and into the submucosa.

Passaro suggested the term 'bypass enteritis' for this condition, on the assumption that colonization of the bypassed loop by colonic bacteria was responsible for gas production, and 2 of his patients apparently responded to antibiotic therapy. Pneumatosis would therefore appear to be a secondary phenomenon in these patients. Frimann-Dahl (1974) likewise considered that his patient developed pneumatosis as a result of chronic volvulus of the sigmoid colon producing secondary mucosal ulceration and allowing gas to enter the tissue planes. A similar observation was made by Nelson (1972), who described a patient with caecal volvulus and radiologically demonstrable gas within the wall of the obstructed caecum. Histological examination showed a fulminant infection of the caecal wall with clostridial gas-forming organisms, presumably secondary to strangulation.

The diagnosis of pneumatosis coli had, however, been made some time before the development of sigmoid volvulus in the first patient described above, and in *Case* 2 the pneumocysts extended beyond the loop of sigmoid colon which had undergone volvulus. There seems little doubt that in these circumstances the volvulus was secondary to pneumatosis. In *Cases* 3 and 4 the possibility exists that volvulus was the primary event, since these patients had presented as emergencies with intestinal obstruction and no preceding history of pneumatosis coli (*Table I*).

The nature of the presenting symptoms in patients with pneumatosis coli frequently results in surgical referral. Misdiagnosis is common (Broecker and Moore, 1977), but an increasing awareness of the condition should allow surgeons to avoid inappropriate surgical intervention (Thomson et al., 1977). Conservative therapy with high flow oxygen is the preferred treatment for symptomatic patients, and surgical resection, which may be followed by recurrence of extensive disease (Thomson et al., 1977), is therefore usually unnecessary. Nevertheless, as our 4 cases show, the rare combination of pneumatosis coli and sigmoid volvulus is potentially dangerous, and we believe that surgical resection is the treatment of choice in these circumstances. •

Conclusion

The attention of surgeons performing oesophageal intubation for benign strictures is drawn to a potentially fatal complication of multiple intestinal perforation resulting from the disintegration of the Celestin oesophageal tube, which is unsuitable for long term use.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Br. J. Surg. Vol. 66 (1979) 807–808

Multiple intestinal perforation due to Celestin tube

J. F. L. SHAW AND G. B. COOMBES*

SUMMARY

Two cases of multiple intestinal perforation caused by the nylon from the core of disintegrating oesophageal Celestin tubes migrating down the alimentary tract are described. It is suggested that Celestin tubes should not be used in patients likely to survive for more than a few months.

Case reports

Case 1: An 80-year-old obese man was intubated with a Celestin tube in October 1977 after regular dilatation had failed to control a 7-cm long peptic oesophageal stricture. He was able to swallow well, but in September 1978 he was readmitted with abdominal colic. At home he had passed per anum a portion of the tube attached to a nylon strand, which he had cut off at the anus. An abdominal radiograph showed evidence of small bowel obstruction, and another portion of the tube in the transverse colon. This was passed the next day, relieving his colic, and again the attached nylon strand was divided. A barium swallow showed the main portion of the Celestin tube still *in situ* in the oesophagus. Eight days later, after episodes of mild colic for one day, he developed peritonitis.

On 27 September 1978, laparotomy revealed 13 separate perforations of the small bowel, from 0·5 to 4 cm long, all on the mesenteric border at apices of loops of bowel. In the lumen was the nylon strand from the Celestin tube, which had cut through the bowel wall. The Celestin tube remnant and the nylon were removed (*Fig.* 1), and the perforations closed. Despite intensive support, the patient died of *Escherichia coli* septicaemia on the fifth postoperative day. At necropsy, linear ulcerations were seen throughout most of the small and large bowel (*Fig.* 2).

Case 2: A 72-year-old woman was treated from 1973 to 1977 with intermittent dilatation of a peptic oesophageal stricture. In August 1977 dilatation caused an oesophageal perforation, which was successfully managed conservatively, and she was subsequently intubated with a Celestin tube. She was well until August and September 1978, when she had two episodes of small bowel obstruction which were managed conservatively. Serial radiographs showed the passage of a portion of the Celestin tube along the colon, and this was subsequently passed per anum.

In October 1978 she was readmitted with peritonitis. Laparotomy disclosed six small bowel perforations along the mesenteric border, which was scarred and shortened along its whole length. A nylon strand was found along the whole length of the bowel: this was divided and removed. The perforations were closed, and she made a good recovery. Three weeks later, the proximal part of the Celestin tube was removed at oesophagoscopy. She remains well, without dysphagia.

Discussion

Celestin (1959), when describing his tube for palliating oesophageal carcinoma, emphasized that the tube was designed for the inoperable malignant stricture. The Celestin tube has, however, been used for relieving benign strictures in patients who are unsuitable for thoracotomy, and in whom self-bouginage or recurrent dilatations have failed.

The Celestin tube was developed as an improvement to the Mousseau–Barbin tube. It was originally made of polythene and had a barrel-shaped funnel. As manufactured at present, it is made of latex with a spiral nylon stiffening core. This has been found to degenerate with time, allowing the core to unravel and pass by peristalsis down the intestine (Mackenzie et al., 1976). This occurred in our cases, and resulted in multiple perforation of the small bowel as a result of a bow-string effect. A similar problem is reported in long term nasojejunal cannulation in infants (Siegle et al., 1976), where duodenal perforations may occur.

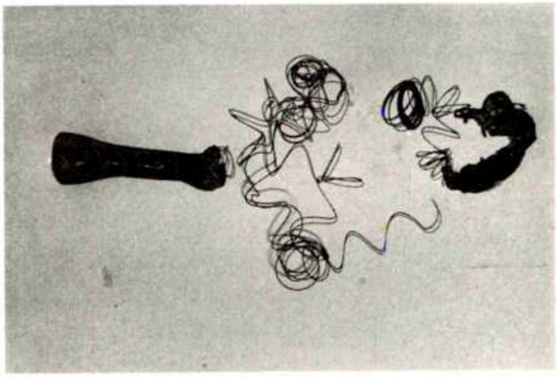

Fig. 1. The degenerate Celestin tube and nylon core after removal.

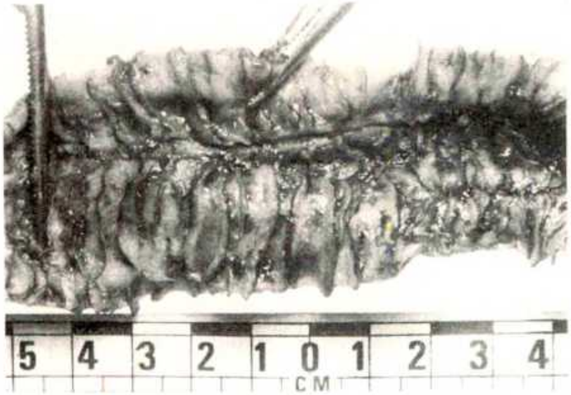

Fig. 2. Linear ulceration of the colon, resulting from the bow-string action of the nylon.

It is suggested that in patients with benign oesophageal stricture requiring intubation, the Celestin tube as at present manufactured should no longer be used. The rim of the V-shaped funnel of the Mousseau–Barbin tube may cause ulceration of the oesophageal mucosa, but the Neoplex of which it is made does not require a nylon stiffening core. Perhaps a Neoplex tube with a barrel-shaped funnel designed by Celestin would be more suitable.

Repeated haemorrhage from a terminal colostomy due to mucocutaneous varices with coexisting hepatic metastatic rectal adenocarcinoma: a case report

R. G. FINEMORE*

THE formation of varices around colostomies and ileostomies is an unusual complication of portal hypertension. In the previously reported cases cited below the cause of portal hypertension has been cirrhosis of the liver secondary to alcoholism or inflammatory bowel disease. We have found no reports describing colonic varices associated with hepatic metastatic carcinoma. The rarely reported feature of bluish skin around the stoma (Cameron and Fone, 1970) and the unreported dilated subcutaneous veins are shown in the Figure. It is well known that if hepatic replacement by neoplastic cells occurs over a long period, portal hypertension may develop with secondary development of varices. It is not known why the varices should occasionally occur in the lower rather than the upper gastrointestinal tract.

Case report

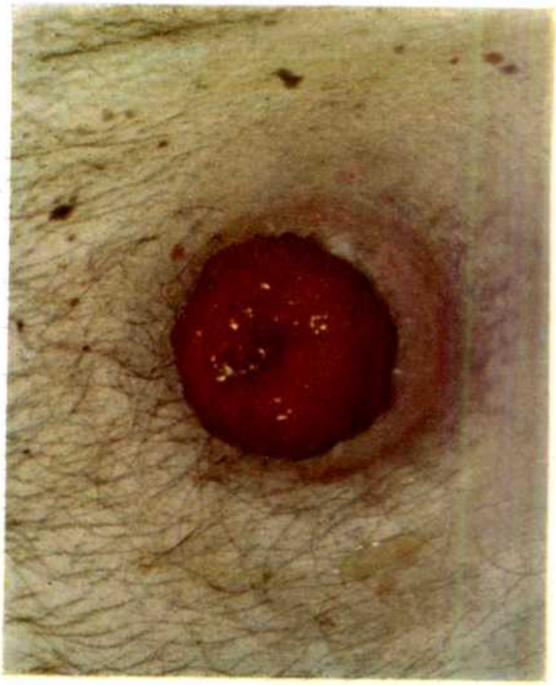
A 67-year-old man presented in April 1978 with profuse bleeding from his terminal colostomy. In February 1975 the patient had had an abdominoperineal resection and left iliac fossa terminal colostomy for a well-differentiated rectal adenocarcinoma. At operation he had had multiple metastatic deposits in the liver. There was no history of alcoholism or inflammatory bowel disease.

Two and a half years postoperatively he developed metastases in the lumbar vertebrae. These were treated with radiotherapy to the lumbar spine. He was also commenced on 5-fluorouracil and prednisone. The back pain was relieved. Three years after his abdominoperineal resection the patient presented with profuse bleeding from his colostomy. Firm pressure was applied to a pad over the colostomy and the bleeding ceased. The colostomy looked normal except for a slight swelling circumferentially around the stoma. The skin colour was normal. Digital examination of the colostomy and barium enema via the colostomy were normal. Close examination revealed the bleeding to be from the mucocutaneous junction of the stoma. Liver function tests were normal except for an elevated serum alkaline phosphatase which could have been due to the known bone metastases.

Over the next 3 months the patient had five episodes of bleeding from the colostomy, each requiring transfusion. On each occasion local pressure was applied and the bleeding ceased, except for one occasion when the bleeding point required an underrun suture at the mucocutaneous junction. Following this sodium tetradecyl sulphate solution was injected subcutaneously around the colostomy. The interval to the next episode of bleeding was prolonged—4 weeks—but when it did occur it was massive, and the patient died. Liver function tests only became deranged 6 weeks before death. During the final 2 months the swelling around the colostomy developed a bluish colour followed by the appearance of subcutaneous dilated veins.

Discussion

It would appear that the slow growth of the well-differentiated tumour in the liver was the cause of portal hypertension. However, as previous reports have suggested (Graeber et al., 1976), stomal varices occur rapidly. Bleeding from the stomal varices, when it occurs, is often massive. The management of this type of bleeding is difficult when the underlying pathological process precludes major surgery such as portasystemic venous shunt. Stomal revision has been used and reported to give adequate control of similar haemorrhages (Cameron and Fone, 1970) but we felt that this was not indicated for this patient. The varices were probably too extensive to achieve any significant lasting benefit from subcutaneous injections of sclerosing solution. We have no doubt that ligation of the bleeding point at the mucocutaneous junction controlled the bleeding when this could not be achieved by local pressure.



Acknowledgement

I gratefully acknowledge the support and advice of Mr I. D. Hunter-Craig, Consultant Surgeon, under whose care this patient was admitted. I am also indebted to Mrs I. Moss who typed the report and Mrs D. Benjamin, Librarian, for her help.

Second Colonoscopy Congress

The Second International Congress on Colonoscopy and Diseases of the Large Bowel will be held on Thursday–Saturday, 6–8 March 1980 at the Americana Hotel, Bal Harbour, Florida. More than 60 papers, numerous panels, endoscopic movies and numerous video-taped colonoscopy and polypectomy demonstrations will be presented by a faculty of twelve speakers, headed by Drs Walter Gaisford, Hiromi Shinya, Jerome Waye and Christopher Williams.

Anyone wishing to attend, present papers or audiovisual material (videotapes or movies), kindly write to the programme chairman, John P. Christie, MD, 7330 SW 62nd Place—Suite 220, South Miami, Florida 33143. Telephone: (305) 667–7440.

Colonic carcinoma at the site of ureterosigmoidostomy: what is the risk?

P. M. THOMPSON, J. T. HILL AND D. A. PACKHAM*

SUMMARY

A case of colonic carcinoma arising 27 years after urinary diversion by ureterosigmoidostomy is reported. This late complication is now well recognized and increasing numbers of cases are being reported. The implications of this patient and the 31 previously reported cases are considered.

DESPITE the well-recognized complications of hyperchloraemic acidosis, chronic renal infections and urinary calculi, the ureterosigmoidostomy was for many years a popular urinary diversion and is still performed by some surgeons. With the introduction of antibiotics and improved anastomotic techniques (Woodruff et al., 1952; Leadbetter and Clarke, 1955) its popularity might have continued but for the development of the ileal conduit in the early 1950s (Bricker, 1950). Nevertheless, there are a large number of surviving patients with ureterosigmoidostomies that were performed over 25 years ago who are at risk of developing carcinoma of the colon at the site of the anastomosis.

Case report

A 30-year-old man presented with a history of vomiting and central abdominal pain for 3 days. When 3 years old he had had a total cystectomy and ureterosigmoidostomy performed for rhabdomyosarcoma of the bladder. Physical examination showed the features of a large bowel obstruction which was confirmed by plain abdominal radiographs.

An emergency laparotomy was performed which revealed an obstructing carcinoma at the ureterosigmoid junction. There were no metastases present. A transverse colostomy was performed followed 1 week later by a sigmoid colectomy and ileal conduit diversion. The colostomy was closed after 3 weeks.

Pathological examination confirmed the location of the tumour at the ureterosigmoid junction and the histology showed a mucinous adenocarcinoma including the full thickness of the muscle coat and the left ureter. The lymph nodes were not involved.

The patient was alive and well at 6-month follow-up.

Discussion

The first report of adenocarcinoma of the colon at the site of a ureterosigmoidostomy came in 1929 from Hammer. Since then there have been a further 30 cases described (Mogg, 1977; Parsons et al., 1977; Sooriyaarachichi et al., 1977).

The incidence of carcinoma after ureterosigmoidostomy is difficult to establish as the numbers are small, many patients are lost to follow-up and it is probable that some cases go unreported (Whitaker et al., 1971). However, it is clear that there is an increased risk and that the tumour occurs in a younger age group. The median age at diagnosis of colonic carcinoma after diversion is 33 years and the corresponding age in the general population is 69 (Sooriyaarachichi et al., 1977). Urdaneta and colleagues (1966) have reported 3 cases of colonic carcinoma in a series of 23 patients after 10 years and Parsons et al. (1977) had 2 cases out of 29 10-year survivors. In relating the incidence to that among the general population at the comparable age the same authors have estimated a 350- to 550-fold increase in the incidence of carcinoma in those who have undergone a ureterosigmoidostomy. From an analysis of a number of series, however, the average increased risk after 5 years has been calculated as 100 times that of the general population (Sooriyaarachichi et al., 1977).

Since the ileal loop was popularized in 1950 there has only been one recorded case of a carcinoma developing in an ileal conduit (Shousa et al., 1978). Although the same mechanism may be involved in the development of such a carcinoma in the ileum as in the colon, it would appear so far that the ileum is less susceptible.

In view of the recent cases reported we suggest that until an accurate incidence is known and the risk assessed caution should be shown in making the ureterosigmoidostomy the long term diversion of choice. In those who have had the operation performed annual sigmoidoscopy or double contrast barium enema limited to the sigmoid should be performed after 5 years.

Acknowledgements

We are grateful to Mr J. L. Dawson, under whose care the patient was admitted, for permission to report his patient.

Postoperative hypoxaemia: oesophagectomy with gastric replacement

D. G. M. BISHOP AND K. C. McKEOWN*

SUMMARY

Pre- and postoperative arterial blood samples were analysed for oxygen partial pressure ($Pa\mathrm{o}_2$) and carbon dioxide partial pressure ($Pa\mathrm{co}_2$) in a consecutive series of 21 patients subjected to two- or three-stage oesophagectomy for carcinoma of the oesophagus. The forced vital capacity (FVC) was measured at the same time.

On the second postoperative day the $Pa\mathrm{o}_2$ showed a fall to 65 per cent of the preoperative value followed by a gradual recovery to 78 per cent on the tenth postoperative day. After 13 weeks the $Pa\mathrm{o}_2$ had recovered to 95 per cent of the preoperative value.

The $Pa\mathrm{co}_2$ decreased in the early postoperative period but had returned to the preoperative level by the tenth day. The FVC showed a trend similar to the $Pa\mathrm{o}_2$ with a reduction to 33 per cent of the preoperative value on the second postoperative day, 52 per cent on the tenth day and 85 per cent after 13 weeks.

ARTERIAL hypoxaemia after operation is usual and follows even trivial procedures. Nunn and Payne (1962) found that after minor procedures under general anaesthesia, hypoxaemia was present for several hours though the $Pa\mathrm{co}_2$ was normal, and thus they and others (Palmer and Gardiner, 1964; Palmer et al., 1965) postulated that the hypoxaemia was due not to simple hypoventilation but to a disturbance in the ventilation–perfusion relationship in the lungs.

Arterial hypoxaemia and mechanical impairment of respiratory function are greatest for upper abdominal surgery, less for lower abdominal surgery and least for non-abdominal surgery (Diament and Palmer, 1966). After upper abdominal surgery, on the first postoperative day $Pa\mathrm{o}_2$ is reduced to 80 per cent of preoperative value, after lower abdominal surgery to 90 per cent and after non-abdominal surgery to 94 per cent. Reduction in forced vital capacity (FVC) is also found but previous workers have not demonstrated a clear correlation between this and $Pa\mathrm{o}_2$.

A comparison of the effect of upper abdominal surgery and thoracoabdominal surgery of the gastrointestinal tract on $Pa\mathrm{o}_2$ (Knudsen, 1970) showed that after upper abdominal surgery the lowest value of $Pa\mathrm{o}_2$ occurred on the third day. The reductions were between 77 and 94 per cent of the preoperative value, with a mean reduction of 84 per cent. Values had returned to normal by the fourteenth day. After thoracoabdominal procedures the lowest values (66–91 per cent, mean 80 per cent) occurred between the fifth and seventh days. Preoperative levels had not been regained at 14 days when the patients were discharged.

In two-stage oesophagectomy patients are subjected to an upper abdominal incision and a right thoracic incision, and in the case of the three-stage operation, a right cervical incision also (McKeown, 1976). On the basis of previous investigations this would be expected to have a marked effect on the respiratory system. This investigation was carried out to determine the duration and severity of arterial hypoxaemia and reduction in FVC following these procedures.

Patients and methods

A consecutive series of 21 patients was investigated after two and three-stage oesophagectomy (*Table I*). Preoperatively the patients received physiotherapy and were instructed in the use of Woolf's bottles which they used pre- and postoperatively. They were also instructed in the technique of postural drainage to assist their cooperation with the physiotherapists in the postoperative period.

Patients were premedicated with Cyclimorph 0·2 mg/kg and atropine 0·4 mg/kg by intramuscular injection 1 h before operation. Anaesthesia was induced with thiopentone up to 4 mg/kg and maintained with nitrous oxide and oxygen supplemented with halothane as required. Muscular relaxation was obtained using tubocurarine. All the operations and anaesthetics were carried out by the authors.

After operation analgesia was achieved by 2-hourly intramuscular injections of 25 mg pethidine until the patient settled. All patients were given oxygen by Ventimask—28 per cent if under 60 years of age and 35 per cent if over 60 years of age. This was continued until the patient could maintain a $Pa\mathrm{o}_2$ of 6·7 kPa while breathing air.

Arterial sampling and subsequent FVC measurements were made with the patients positioned so that the chest was 45° to the horizontal. Before sampling the patients breathed room air for 90 min and no analgesic drugs were administered in the 6-hour period prior to measurement. Arterial samples were obtained from the radial artery using a Macbick arterial blood sampling kit. The analysis of the arterial blood was carried out immediately. FVC was measured immediately after the arterial sampling. Both procedures were carried out on the day before operation and on postoperative days 2, 4, 6, 10, 14, 21 and 91.

For blood gas analysis an IL 213 analyser was used and was maintained solely for this investigation. The analyser was calibrated according to the maker's instructions using standard gas mixtures. The FVC measurements were obtained with a standard Vitalograph, the best of three attempts being the value taken. The samples and measurements were all taken by one person (D. G. M. B.). Statistical analysis was by paired *t* tests.

Table I: DETAILS OF THE CASE SERIES

	Age (yr) (±s.d.)	Two-stage operation	Three-stage operation
Males	61·7±13·8	4	6
Females	67±7·5	5	6

Results

The $Pa\mathrm{o}_2$ fell sharply after operation and then gradually increased (*Fig.* 1). The value of $Pa\mathrm{o}_2$ fell significantly after operation ($P<0{\cdot}0001$) in all cases and then increased significantly after each time interval. At the end of 91 days the $Pa\mathrm{o}_2$ values were significantly below their preoperative value ($P<0{\cdot}0001$) for the female patients, but were not significantly reduced in the case of the male patients.

The value of $Pa\mathrm{co}_2$ fell after operation, but by the tenth postoperative day the values obtained were not significantly different from the preoperative value (*Fig.* 2).

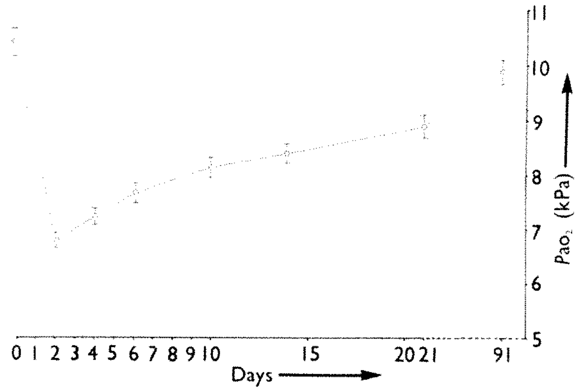

Fig. 1. Course of mean ± s.e. mean of $Pa\text{O}_2$ over time.

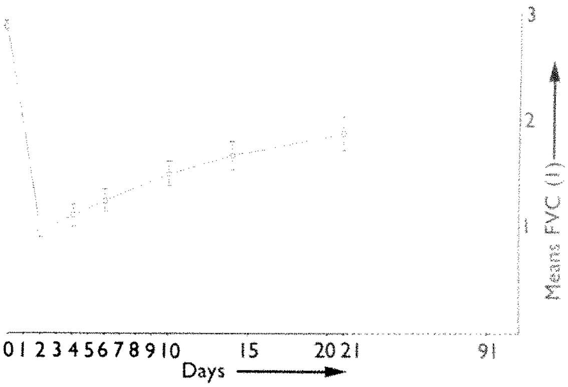

Fig. 3. Course of mean ± s.e. mean of FVC over time.

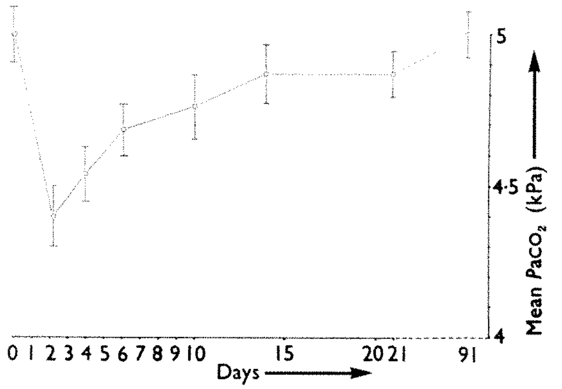

Fig. 2. Course of mean ± s.e. mean of $Pa\text{CO}_2$ over time.

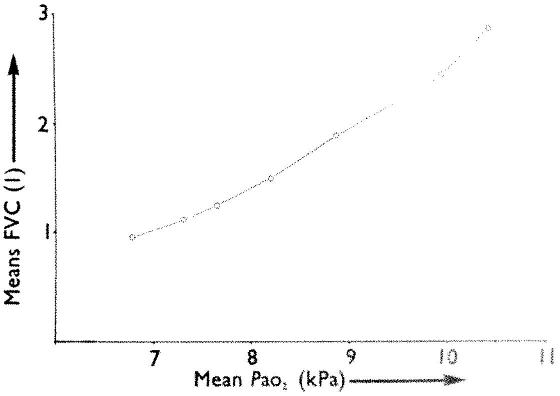

Fig. 4. Relationship between mean FVC and mean $Pa\text{O}_2$ between 1 and 91 days.

The FVC fell sharply after operation and then gradually increased (*Fig.* 3). The significance of the fall on the second postoperative day was $P < 0{\cdot}0001$ in all cases. At 91 days the value was still significantly below the preoperative value ($P < 0{\cdot}0001$).

The mean value of FVC was plotted against the mean value of $Pa\text{O}_2$ for each postoperative day (*Fig.* 4). Both values were seen to increase in a similar manner with the passage of time.

Discussion

Hypoxaemia extending beyond the immediate postoperative period has been attributed to a variety of factors.

After partial gastrectomy in patients with normal respiratory function preoperatively there is a reduction in vital capacity to 45 per cent of its preoperative value with a gradual increase to 76 per cent by the fifth postoperative day (Palmer et al., 1965). Movements of the thorax, abdomen and diaphragm can be restricted by the mechanical inefficiency caused by incision of muscles and by the restrictive effects of bandages, gut distension and pneumoperitoneum (Anscombe, 1957).

Pain from the surgical incision is associated with a decrease in vital capacity and reduction in the efficiency of coughing and the ability to make maximal inspiratory efforts. Effective pain relief would be expected to ameliorate these effects. Spence and Smith (1971) showed that segmental thoracic epidural analgesia after upper abdominal surgery reduced hypoxaemia and the alveolar–arterial oxygen difference ($D(\text{A–a})P\text{O}_2$) when compared with the use of morphine (10 mg intramuscular injection) given on patient demand. By the fifth postoperative day patients in the epidural group had achieved their preoperative $Pa\text{O}_2$ levels whereas the morphine group had not. Bromage (1967) reported that segmental thoracic epidural analgesia after upper abdominal surgery restored the vital capacity to a level between 70–100 per cent of its preoperative value and restored the functional residual capacity (FRC) to normal.

The pulmonary mechanism by which hypoxaemia is produced after operation is thought to be due to a combination of ventilation–perfusion mismatch and shunt. These in turn are secondary to changes in FRC and the closing volume (CV) (Milic-Emili et al., 1966; Spence and Alexander, 1972).

Expiration from total lung capacity to residual volume (RV) is normally accompanied by small airway closure in the dependent parts of the lung where transpulmonary pressure (TPP) is highest. The lung volume at which this occurs is the CV, which in young people normally lies close to the RV. Pain, with its attendant muscle spasm, causes an increase in TPP which results in a decrease in FRC and an increase in CV. This effect is enhanced by obesity, age and mechanical pressures due to bandages, gut distension and pneumoperitoneum. In young people small airway closure does not occur during normal tidal breathing, but in the circumstances mentioned above, or in the presence of lung disease, the CV can lie within the range of normal tidal breathing. Intermittent airway closure during tidal breathing leads to ventilation–perfusion mismatch and if TPP is high enough some small airways may remain closed throughout the respiratory cycle, resulting in shunt (Leblanc et al., 1970). It has been shown that $D(\text{A–a})Po_2$ increases as the difference between CV and FRC decreases. The $D(\text{A}-\text{a})Po_2$ also increases as the FRC decreases, and since the FRC alters more after operation than the CV, it is the more important factor of the two (Alexander et al., 1973).

The present study shows that the combination of an upper abdominal incision and right thoracic incision produces a disturbance in respiratory function that is greater in duration and extent than that produced by either of these incisions on their own. In addition to the causative factors already mentioned, there is another, unique factor present in this series, i.e. the transposed stomach, an elastic bag of variable size which is open to the atmosphere. The presence of this 'hydropneumothorax' could account for the observed reduction in the FVC below the preoperative level at 13 weeks after operation and also for the reduction in the Pao_2 of the female patients at 13 weeks. The Pao_2 of the male patients at 13 weeks had returned to preoperative values but the FVC of the male is, of course, larger to start with than that of the female.

The close association in time of changes in Pao_2 and FVC is surprising as previous investigators have not shown any simple relationships between postoperative hypoxaemia and restrictive impairment of respiratory function as shown by FVC, although the association with FRC is well known.

Acknowledgements

This project was supported by a grant from the Research Grants Committee of the former Newcastle Regional Hospital Board to purchase and maintain the IL 213 and Vitalograph. The Macbick arterial blood sampling kits were kindly donated by C. R. Bard International, Pennywell, Sunderland.

The statistical analysis and computer program were kindly carried out by Mrs J. D. Cranage of the Department of Statistics, Northern Regional Health Authority.

The preoperative detection of internal mammary lymph node metastases in breast cancer*

M. P. OSBORNE, K. JEYASINGH, R. F. JEWKES AND IAN BURN†

SUMMARY

The internal mammary lymph node chain has been studied in patients with breast cancer by radioisotope imaging. The technique enabled the study of lymph node function in an area inaccessible to clinical examination or lymphography.

Thirty-four patients with breast cancer have been studied by injecting the posterior sheath of the rectus abdominis muscle, in the subcostal region, with technetium-99^{m}*-labelled stannous phytate and subsequently imaging the anterior thorax. Lymph node metastases were diagnosed in 13 patients (38 per cent) in whom a suppressed uptake of the isotope by the internal mammary lymph nodes was observed. Eighteen patients (53 per cent) had normal scans and in 3 patients (9 per cent) the examination was technically unsatisfactory. Histopathological correlation of internal mammary node biopsy with the preoperative scan confirmed the scan findings in all but one case in which this was carried out. Radioassay of internal mammary lymph nodes confirmed that the agent was localized in them and that uptake was suppressed in the presence of metastases.*

Twenty-three patients in this study underwent sequential scanning using first ^{99}*Tc*^{m}*-labelled stannous phytate and subsequently* ^{99}*Tc*^{m}*-labelled antimony sulphide colloid. The latter agent was able to demonstrate the anatomical presence of nodes when a suppressed uptake had initially been observed using* ^{99}*Tc*^{m}*-labelled stannous phytate.*

Internal mammary lymphoscintigraphy may be of value in the preoperative staging of breast cancer.

THE spread of breast cancer to the regional lymph nodes is of importance in determining the treatment of local disease by surgery and radiotherapy as well as being the most accurate prognostic indicator (Fisher et al., 1969).

The internal mammary lymph nodes (IMN) are an important site of regional lymph node spread (Handley and Thackray, 1954). One-quarter of all patients with operable breast cancer have IMN metastases. A small proportion of patients have this as the sole site of nodal metastatic disease; if this site is not taken into account, errors in staging will occur.

The IMN are not accessible to clinical examination or lymphography and so are not taken into account in preoperative staging. In order to improve this aspect of staging, IMN isotope imaging has been studied in patients with breast cancer.

Patients and methods

Thirty-four patients with breast cancer were studied; the tumours were predominantly located centrally or in the inner quadrants. Full TNM clinical staging with blood count, liver function tests, chest radiography, skeletal scintigraphy and urinary hydroxyproline estimation was carried out before treatment. IMN scanning was carried out on admission.

Technique of internal mammary lymphoscintigraphy

Single agent scan: A preparation of ^{99}Tc^{m}-labelled stannous phytate (^{99}Tc^{m} SnP) was injected into the posterior sheath of the rectus abdominis muscle in the subcostal region on the same side as the tumour (Osborne, Jewkes et al., 1978). This site of injection allows radioisotopic imaging of the IMN chain on the same side as the injection (Rossi and Ferri, 1966; Schenck, 1966). The agent was prepared from a kit (Diagnostic Isotopes Inc.) by adding 2–4 ml of sterile, pyrogen-free, sodium pertechnetate to a vial containing 10 mg of sodium phytate and 1·0 mg of stannous chloride. Three hundred microCuries of ^{99}Tc^{m} SnP in 0·2 ml were injected.

Some patients also received an injection of ^{99}Tc^{m} SnP into the contralateral posterior rectus sheath in order to image the contralateral IMN chain on the 'normal' side.

Imaging was carried out 2 h after injection.

Dual agent 'sequential' scans: Following an injection of ^{99}Tc^{m} SnP and subsequent IMN imaging 2 h later, a preparation of ^{99}Tc^{m}-labelled antimony sulphide colloid (^{99}Tc^{m} SbSC) was injected into the posterior sheath of the rectus abdominis muscle on the same side as the tumour near the site of the previous injection. A further image was obtained 2 h after this injection, the entire procedure being carried out in a 4-h period. ^{99}Tc^{m} SbSC was prepared from a kit (Philips–Duphar BV) by adding 2–4 ml of sterile, pyrogen-free sodium pertechnetate solution to a vial containing antimony trisulphate. The vial was heated in a water bath for 15 min, cooled and citrate buffer (pH 12·8) added. Three hundred microCuries of ^{99}Tc^{m} SbSC in 0·2 ml were injected.

Dual agent lymphoscintigraphy was carried out as the diagnosis of IMN metastases depends on observing a suppression of uptake of ^{99}Tc^{m} SnP and there might be doubt as to the anatomical presence of these nodes. Previous laboratory studies of experimental models (Osborne, Jeyasingh et al., 1978) have shown that lymph nodes *partially* replaced by metastatic tumour will take up ^{99}Tc^{m} SbSC and may be imaged.

Gamma camera imaging: Images of the anterior thorax and upper abdomen were obtained using a wide-field, high resolution gamma camera (NE 8960) with online computerized data processing facilities (Varian Data Analyser). Patients were imaged for 3 min using a parallel-hole collimator with a pulse height analyser setting of 140 KeV. Anatomical landmarks were shown using an americium-241 10 mCi marker to identify exactly the site of internal mammary lymph nodes. The scans were presented as a computer output image using an electrostatic plotter after suitable background subtraction.

Interpretation of lymphoscintiscans

Single agent scan: A lymphoscintiscan was interpreted as normal when localization of ^{99}Tc^{m} SnP was observed in the upper intercostal spaces in the parasternal region on the same side as the tumour (*Fig.* 1*a*). An abnormal scan, indicating the presence of lymph node metastases, was interpreted as such when a suppressed localization of the radioisotope was observed in the upper intercostal spaces in the parasternal region on the same side as the tumour (*Fig.* 2*a*). The correct placement of the injection was confirmed by visualization of the xiphoid or lower internal mammary nodes. Incorrect siting of the injection resulted in localization of the isotope in axillary or inguinal regional nodes if too superficial, or an image of the peritoneal cavity if too deep.

Dual agent 'sequential' scans: Sequential scans, imaging first after injecting ^{99}Tc^{m} SnP and subsequently after ^{99}Tc^{m} SbSC,

Fig. 5. Fifty-one-year-old patient with T2a N0 M0 carcinoma (T) in the left lower inner quadrant. *a*, Normal internal mammary lymphoscintiscan using $^{99}\mathrm{Tc}^{m}$ SbSC. Uptake of the isotope is seen in the internal mammary nodes on the same side as the tumour and on the contralateral side. *b*, Low power (×22·5) photomicrograph showing two tumour metastases in the left second intercostal space internal mammary node.

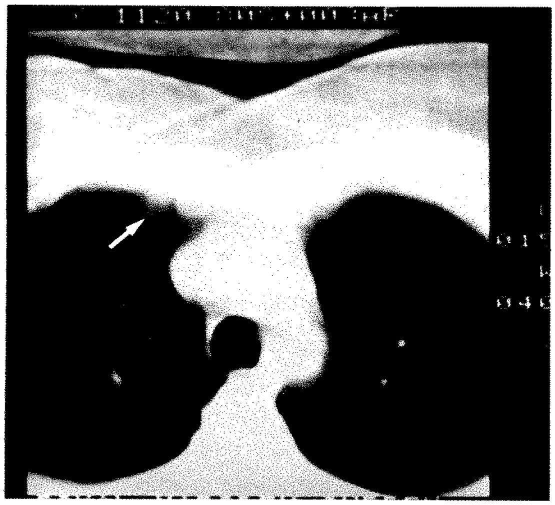

Fig. 6. Computer-assisted tomogram of the thorax of a 28-year-old patient who presented with a right axillary node mass. Sequential scanning suggested IMN metastases. The arrow points to a mass projecting into the anteromedial part of the right hemithorax at the level of the second intercostal space, suggesting enlargement of an internal mammary node.

Table I: INTERNAL MAMMARY LYMPH NODE RADIOASSAY FOLLOWING $^{99}\mathrm{Tc}^{m}$ SnP SCANNING EXPRESSED AS SPECIFIC ACTIVITIES (c min^{-1} g^{-1})

Target (IMN) (c min^{-1} g^{-1})	Non-target (pectoral muscle) (c min^{-1} g^{-1})	Target: non-target ratio	IMN histology
167 930	194	866 : 1	Normal
341	383	0·89 : 1	Metastasis
392	383	1·02 : 1	Metastasis

were interpreted on the basis of the previous laboratory studies. A sequential scan was interpreted as being normal if there was localization of both agents in a similar pattern in the upper intercostal spaces in the parasternal region on the same side as the tumour. An abnormal scan, indicating the presence of IMN metastases, was interpreted as such if a suppressed uptake of $^{99}\mathrm{Tc}^{m}$ SnP was observed on the first scan, the subsequent $^{99}\mathrm{Tc}^{m}$ SbSC scan showing uptake by the upper IMN on the same side as the tumour (*Fig.* 3), thereby confirming the anatomical presence of nodes.

Lymph node radioassay

In a small number of cases where single agent IMN scanning using $^{99}\mathrm{Tc}^{m}$ SnP was carried out within 24 h of operation, lymph nodes were radioassayed in a well scintillation counter with control tissue of pectoral muscle (*Table I*). The background was subtracted and the results expressed as the specific activity —radioactive counts per unit time per unit wet weight of tissue (counts per minute per gramme—c min^{-1} g^{-1}).

Histopathological correlation

Internal mammary lymph nodes on the same side as the tumour were biopsied at the time of mastectomy in suitable operable patients. The nodes were fixed in formol saline, step-cut (20 μm) serially sectioned and stained with haematoxylin and eosin. Sections were examined for metastases.

Results

Single agent scans

Thirty-four patients with breast cancer were studied using $^{99}\mathrm{Tc}^{m}$ SnP. Eighteen patients (53 per cent) had normal scans and 13 patients (38 per cent) had abnormal scans, suggesting the presence of IMN metastases. Three patients (9 per cent) had a technically unsuccessful scan due to misplacement of the injection. No complications were observed in this study.

Fifteen patients (50 per cent) with technically satisfactory scans (11 normal and 4 abnormal) had histopathological correlation between the internal mammary nodes biopsied at operation and the preoperative scan. Ten out of 11 *normal* scans were confirmed to be correct (e.g. *Fig.* 1), one was incorrect and found to have a subcapsular sinus micrometastasis on serial section (*Fig.* 4). Four patients with *abnormal* scans all were confirmed histologically to have internal mammary node metastases (e.g. *Fig.* 2). The patient illustrated in *Fig.* 2 had a T0 N0 M0 centrally positioned infiltrating carcinoma in the right breast which was impalpable and was detected in a screening programme by mammography. Biopsy of the IMN from the right second and third intercostal spaces confirmed the presence of metastases, the axillary lymph nodes were not involved.

In those patients in whom the contralateral IMN were scanned (e.g. *Fig.* 2) suppressed uptake was observed, but biopsy of these nodes to confirm the presence of contralateral IMN spread of tumour was not possible as these nodes are not accessible during mastectomy.

Dual agent 'sequential' scans

Twenty-three patients underwent sequential scanning using ^{99}Tc^{m} SnP and ^{99}Tc^{m} SbSC. Eleven patients (46 per cent) had normal scans where both agents showed a similar localization of the isotope in the upper intercostal spaces on the same side as the tumour, 8 patients (33 per cent) had an abnormal scan where a different pattern of uptake was observed between the two agents (*Fig.* 3). Five patients (21 per cent) had uninterpretable scans due to misplacement of one of the injections. In this series 8 patients with technically satisfactory scans (6 normal and 2 abnormal) had histopathological correlation of the internal mammary nodes biopsied at operation with the preoperative scan. The presence of lymph node metastases, demonstrated by an abnormal sequential scan where ^{99}Tc^{m} SbSC had shown the anatomical presence of the ipsilateral IMN and subsequently confirmed by IMN biopsy, is illustrated in *Fig.* 5. No false positive or negative findings were encountered in this small subseries.

One patient, who presented with a large metastatic axillary node mass, had an abnormal internal mammary sequential scan and a computer-assisted tomogram at the level of the second intercostal space (*Fig.* 6) showed a mass in the region of the internal mammary nodes projecting into the right pleural space.

Lymph node radioassay

Radioassay studies of nodes removed soon after IMN scanning using ^{99}Tc^{m} SnP confirmed that normal internal mammary nodes localized the isotope and that the presence of node metastases suppressed localization (*Table I*). The specific activity of normal lymph node was 866 times greater than that of nearby non-target tissue (pectoral muscle). The specific activity of lymph nodes containing metastases was similar to non-target tissue, confirming the marked suppression of uptake.

Discussion

Internal mammary lymph node imaging enables preoperative study of an important area of regional lymph node drainage in breast cancer inaccessible to clinical examination or lymphography. Lymph node imaging was first described following the observation that interstitially injected colloidal radiogold (^{198}Au) was selectively localized in regional lymph nodes (Sherman and Ter-Pogossian, 1953). This agent carried the serious disadvantage of a high radiation dose at the injection site due to a long half-life and beta-particle emission. The isotope technetium-99^{m}, derived from molybdenum, was introduced (Harper et al., 1965), and with a short half-life and gamma emission it had ideal imaging characteristics. ^{99}Tc^{m} sulphur colloid was utilized for lymph node imaging (Hauser et al., 1969) and subsequently Ege (1976) used the antimony sulphide colloid made by a modification of the method of preparing sulphur colloid (Garzon et al., 1965) which yielded a smaller particle size.

Experimental studies using a transplantable tumour model (Rd/3 rat tumour), which metastasized to the regional lymph nodes, showed that ^{99}Tc^{m} SbSC was not as sensitive an agent in detecting lymph node metastases as ^{99}Tc^{m} SnP (Osborne, Jeyasingh et al., 1978). ^{99}Tc^{m} SnP is not a colloid *in vitro* but forms a microcolloid *in vivo* by chelation with calcium ions (Subramanian et al., 1973).

The results of the clinical studies reported here suggest that ^{99}Tc^{m} SnP is suitable for internal mammary lymph node imaging and can detect internal mammary lymph node metastases. Using this agent alone, 38 per cent of the patients studied had abnormal scans; the expected incidence of internal mammary node metastases for central and inner quadrant tumours is 31 per cent (Handley, 1975). Histopathological study of the internal mammary nodes showed good correlation with the preoperative scans with only one false negative finding. A very high uptake of ^{99}Tc^{m} SnP was observed in a node which contained a subcapsular sinus micrometastasis (*Fig.* 4); marked follicular hyperplasia was also present. The significance of micrometastatic nodal disease is questionable as such cases have been shown to have a similar prognosis to patients with negative nodes (Pickren, 1961; Fisher et al., 1978).

One of the patients in the present study (*Fig.* 2) had a node negative axilla and involvement of the internal mammary chain. Those with the internal mammary chain as the sole site of nodal involvement form about 10 per cent of patients with central and inner quadrant tumours (Handley, 1954). In some patients in whom a contralateral injection was given suppression of IMN uptake was observed, suggesting crossover spread of tumour to the contralateral IMN. Crossover of injected colloids has been observed at the xiphoid and manubrial levels (Ege, 1976) and at post-mortem the spread of tumour to the contralateral IMN chain has been seen (Osborne and Bradley, 1979, unpublished data). These observations may have practical importance in the planning of radiotherapeutic fields.

Measurement of lymph node specific activity of injected ^{99}Tc^{m} SnP by radioassay has shown that normal lymph nodes localized the agent and that the presence of lymph node metastases suppresses this localization. Experimental autoradiographic studies have shown that regional lymph node medullary macrophages appear to take up radiolabelled colloidal agents (Mosley et al., 1978). The question whether the suppressed nodal uptake of radiolabelled colloids in the presence of node metastases is due to tumour replacement of the lymph node, mechanical obstruction or a factor produced by the tumour which suppresses macrophage activity has not yet been answered.

One of the major problems in the interpretation of lymphoscintiscans is that a suppressed or absent uptake could be interpreted as either representing lymph node metastases or an anatomical absence of lymph nodes. Using a model in which partial lymph node replacement by tumour reliably occurred, it was shown that ^{99}Tc^{m} SbSC was taken up to a greater degree than ^{99}Tc^{m} SnP and such nodes could be imaged by sequential scanning using their differential uptake to identify their anatomical presence (Osborne, Jeyasingh et al., 1978). The results of sequential scanning in this series suggest that partially involved lymph nodes could be identified using ^{99}Tc^{m} SbSC (*Fig.* 5). Eight patients with suppressed IMN uptake using ^{99}Tc^{m} SnP showed subsequent uptake using ^{99}Tc^{m} SbSC (*Fig.* 3) and this was confirmed histologically in 2 patients. The presence of total nodal replacement by metastatic tumour might raise a problem as no colloidal agent would be localized by such nodes, but computer-assisted axial tomography may be of value (*Fig.* 6) in identifying enlarged IMN.

A method of detecting internal mammary lymph node metastases will result in an improvement in the local staging of breast cancer and will thereby allow a more rational approach to treatment. Without reference to the internal mammary chain serious errors in nodal staging can occur. Although it is possible routinely to biopsy IMN, this is not always convenient and cannot give the complete picture as such nodes may be small and difficult to find. Biopsy cannot give information about contralateral spread to the opposite IMN chain. With an increasing trend towards less radical surgery such a technique may be the only means of detecting IMN metastases without resort to a separate biopsy procedure.

Internal mammary lymphoscintigraphy can give useful information about the regional lymph node drainage in cancer of the breast and further studies are required to evaluate its accuracy.

Acknowledgements

We are grateful to Professor A. J. Harding Rains who made available the facilities of the Department of Surgery. We are indebted to Dr J. Husband of the Royal Marsden Hospital, Sutton, for the CT scan. The histopathology was checked by Dr A. Vincenti.

The work was carried out while one of the authors (M. P. O.) had tenure of a Wellcome Trust Surgical Fellowship, and further financial support was given by the North-West Thames Locally Organized Research Scheme.

Granular cell myoblastoma of the breast: a report of 2 cases

M. MCCRACKEN, P. B. HAMAL AND E. A. BENSON*

SUMMARY

Two cases of granular cell myoblastoma of the breast are presented occurring in women aged 20 and 22 years. The clinical findings, mammographic and naked eye appearances suggested carcinoma. The difficulties of diagnosis and the pathogenesis of this rare tumour are discussed. A definitive histological diagnosis of an apparently malignant breast lump, particularly in a young woman, is mandatory before proceeding to major surgery.

Case reports

Case 1: A 22-year-old student from Indonesia was referred to the combined breast clinic having noticed a lump in the right breast for 3 years. More recently this had been associated with skin dimpling. There was no family history of breast disease, nor any relevant past history. She had been taking Microgynon for 2 years before attending the clinic. There had been no pregnancies. On examination skin dimpling was noted in the upper outer quadrant of the right breast and beneath the dimpling a hard lump measuring 2 × 2 cm was felt; the lump was not freely mobile. No lymph nodes were palpable in the axilla. Despite the patient's age a diagnosis of probable carcinoma of the breast was made. A mammogram was performed and reported as showing 'a vague density with linear extension to the overlying thickened and dimpled skin. No actual mass seen nor any calcification identified. However, malignancy is very likely.' At excision biopsy the surgeon reported the naked eye appearance to be that of a contracting carcinoma and this was also the opinion of the pathologist. A frozen section was not performed, but urgent paraffin section revealed a granular cell myoblastoma.

Pathology

Macroscopically the tumour was a creamy-white colour and merged imperceptibly into the breast parenchyma. *Microscopically* it showed compact tumour cells separated by a variable degree of fibrous tissue. Foci of breast tissue were present in the substance of the tumour (*Fig.* 1). The tumour cells were typically large and polygonal with a small regular vesicular nucleus and abundant granular cytoplasm which appeared eosinophilic on ordinary H and E stain. The cytoplasmic granules stained positively with PAS for mucopolysaccharide and with Sudan IV for fat. Electron microscope studies performed on formalin-fixed material confirmed the paraffin section findings as shown by the following report:

'The sections show large cells with numerous cytoplasmic granular inclusions of variable electron density and composition, many of which are membrane-bound. The cells are aggregated in discrete islands linked by basement membrane. The nuclei show shallow indentations, peripheral condensation of chromatin and prominent nucleoli.

'Study of the cytoplasmic inclusions at higher magnifications shows that they are of complex morphology and contain electron-dense granular or amorphous material as well as small clear vesicles.

'The ultrastructural appearances are in entire agreement with those in previously described electron microscopical studies of granular cell myoblastoma.'

Case 2: A 20-year-old student was referred with a lump in the upper inner quadrant of the right breast, which was described by the referring physician as fixed to the pectoral muscle, 'almost as though within the muscle itself'. When seen in the clinic muscle fixation was not confirmed, the lump being hard and irregular but mobile, and there were no overlying skin changes. Mammography was not arranged as the clinical impression was of a benign lesion, probably a fibroadenoma. Excision biopsy revealed a 1-cm well-circumscribed spherical nodule, the cut surface of which was homogenously white and hard (*Fig.* 2).

Pathology

Macroscopically this tumour had a fibrous pseudocapsule but was otherwise similar in all respects to the first specimen.

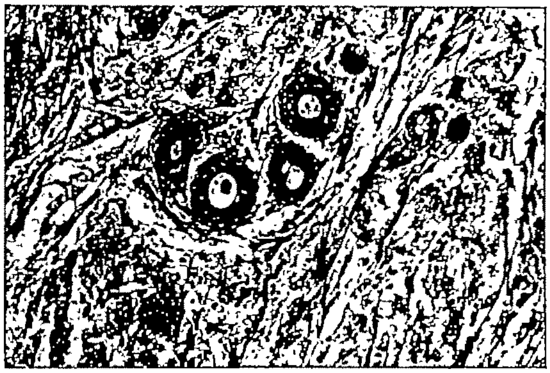

Fig. 1. Presence of breast tissue in the midst of tumour cells (centre). Note the granularity of cells. (PAS. ×100.)

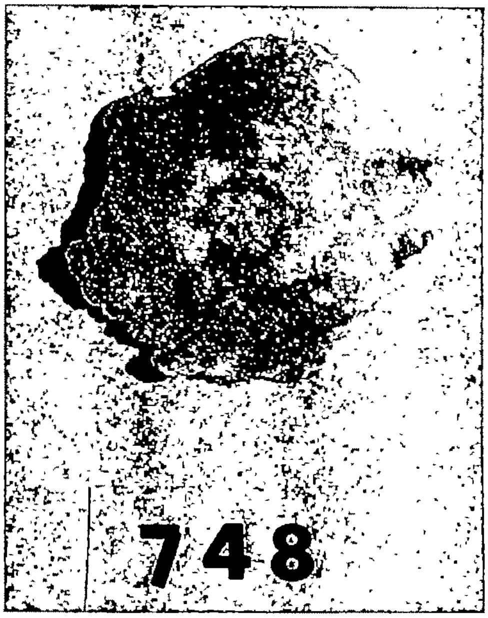

Fig. 2. Gross features of the tumour of *Case* 2. Well-circumscribed spherical mass with regular margins and uniformly homogenous.

Discussion

Carcinoma of the breast in a woman of 22 is a rare occurrence. Nevertheless the clinical signs in *Case* 1 indicated that carcinoma was the probable diagnosis. Mammography in nulliparous young women is rarely helpful, as the breast disc is too dense to allow of accurate interpretation. However, despite this the radiologist's opinion confirmed the clinical diagnosis of cancer. Only 2 cases of mammographic findings in granular cell myoblastoma have previously been reported (Zuckerman, 1965; Turnbull et al., 1971). Zuckerman demonstrated how this tumour could mimic carcinoma with skin thickening associated with a shadow which had the dendritic properties and dense appearance of a scirrhous cancer. In Turnbull's case the mammogram was reported as benign.

To date less than 50 cases of granular cell myoblastoma of the breast have been reported, none with a correct preoperative diagnosis. Of the 15 cases documented by Mulcare (1968) a diagnosis of cancer was made on 7 occasions (on the basis of either skin or deep fixation), another 7 were diagnosed as fibroadenoma, while one granular cell myoblastoma was found in another part of a breast which had been removed for cancer. The tumour has been reported in patients ranging in age from 21 to 70 years, 3 cases being male (Mulcare, 1968; Leroy et al., 1972; Sussman et al., 1973). In 2 cases mastectomy was performed on the basis of the gross characteristics (Friedman and Hurwitt, 1966).

It has been suggested (Sussman et al., 1973) that needle aspiration is a satisfactory way of establishing the diagnosis. However, this method cannot be recommended, as even in the hands of a proponent of aspiration cytology a benign lesion was all that could be diagnosed, excision biopsy being necessary to reach a definitive diagnosis (Lowhagen and Rubio, 1977).

The place of frozen section in diagnosis of this type of tumour has also caused dispute. Many workers have found it unreliable and indeed dangerous—a diagnosis of carcinoma or fibrosarcoma having been made—with resultant unnecessary mastectomy (Byrne and Dean, 1960; Friedman and Hurwitt, 1966; Mulcare, 1968). Nevertheless, Turnbull et al. (1971) maintained that a reliable diagnosis could be made by this method, and with improved frozen section technique the histopathologist should be capable of diagnosing the lesion.

It is apparent, therefore, that for a tumour presenting in a young woman which is clinically, mammographically and to the naked eye a carcinoma, treatment should initially be by excision biopsy alone until the pathologist's report is available. Provided that a margin of surrounding healthy tissue has been excised (because some of these tumours grow into fascial and muscle planes), no further treatment is indicated should the tumour prove to be a granular cell myoblastoma.

Myoblastomas are rare tumours and were described originally in the tongue by Abrikossoff in 1926. Forty per cent occur in the tongue, but they have also been described in the skin, gastrointestinal tract, respiratory tract, uterus, central and peripheral nervous systems and connective tissue as well as the breast. They are sometimes multiple (Crawford and De Bakey, 1951; Schmidt et al., 1959; Moscovic and Azar, 1967) and not uncommonly regress spontaneously, as do neural tumours. Malignant variants have been described (Ravich et al., 1945; Gamboa, 1955; Krieg, 1962), but these are very rare, and apart from the case reported in 1953 by Crawford and De Bakey in which lesions were noted simultaneously in the lung, liver, coeliac nodes and left breast without an obvious primary tumour, no case of malignant myoblastoma has been described in the breast. The importance of the tumour lies in the fact that it closely mimics breast cancer, both clinically and on naked eye examination.

Various theories have been propounded as to the true nature of the granular cell myoblastoma, whose cellular origin is controversial. The term myoblastoma was coined by early writers because of the tumour's association with voluntary muscle, e.g. the tongue (Svejda and Horn, 1958; Fisher and Wechshler, 1962). Aparicio and Lumsden in 1969, using histochemical and electron microscopy studies, concluded that myoblastoma were 'slow growing new growths whose cells have leiomyogenic affinities perhaps peculiar to special skeletal muscle structures'. However, in 1971, as a result of electron microscopy and cytochemical studies of seven typical granular cell myoblastomas (one of which was in the breast), Sobel et al. (1971), while stating that a definite conclusion about the nature of granular cell myoblastomas was not possible, postulated that the myoblastoma was a tumour-like lesion of Schwann cell origin which represented a reactive cellular response or, more likely, a true neoplasm. In later work Sobel concluded that the tumour was derived from an undifferentiated mesenchymal cell that may also be the precursor of the schwannoma, thus making the schwannoma and myoblastoma related to each other as well as to the fibroblast (Sobel et al., 1973).

Light microscopy is quite adequate to establish a diagnosis, which may be reinforced by cytochemical stains. Electron microscopy studies are only required as research tools to study the histogenesis of the tumour.

Salmonellosis associated with late rupture of an aortofemoral bypass graft

A. R. SCOTT AND D. M. HOPE*

SUMMARY
Salmonella infection is a rare cause of rupture of the atherosclerotic abdominal aneurysm. A case never previously reported is presented in which salmonella infection occurred involving an aortofemoral bypass graft which had been inserted 10 years previously. The infection caused a leak in the region of the graft which presented as a haematoma in the thigh.

LARGE vessels such as the aorta are normally very resistant to infection. This resistance, however, is impaired in the presence of vascular anomalies and other arterial lesions such as atherosclerosis and syphilitic arteritis (Ten Eyck and Wellman, 1959). There are 23 reports in the literature (Kanwar et al., 1974; Porschen et al., 1977) of salmonella infections occurring in patients with atherosclerotic abdominal aortic aneurysms. Salmonella infection, however, has never previously been reported occurring in a synthetic vascular graft.

Case report

R. R., a 63-year-old male, had been fit and well following a bilateral aortofemoral bypass graft and sympathectomy in 1968. He presented to the Royal Hobart Hospital on 22 May 1978 complaining of pain in his right loin and right hypochondrium. The symptoms rapidly improved and a cholecystogram confirmed the presence of gallstones. He was allowed home but was readmitted the next week complaining of pain in the left iliac fossa with some radiation to the groin. His doctor reported that the patient had had a swinging pyrexia and had lost 2 stone (13 kg) in weight over a period of about 3 weeks.

On admission the adductor region of the left thigh was markedly swollen and tender. The hip remained flexed at about 45° and there was a swinging temperature ranging from 36·9 °C to 39 °C. Blood cultures grew *Salmonella choleraesuis* (variant Kuzendorf), this identification being confirmed by the Salmonella Reference Laboratory (Institute of Medical and Veterinary Science, Adelaide). The organism was sensitive to chloramphenicol, ampicillin and gentamicin. No salmonellae were isolated from stool and urine cultures despite multiple cultures. Initial X-ray of the spine showed mild degenerative changes only, although later tomograms did suggest a defect in the upper anterior cortex of L1. Barium meal, gastroscopy, bone scan and ultrasound did not aid the diagnosis.

The patient was treated with ampicillin and then chloramphenicol and he clinically started to improve, although he continued with a low grade pyrexia and the left thigh remained swollen. Three weeks after admission the swelling of the thigh had become fluctuant and a further fluctuant area was present just medial to the anterior superior iliac spine. Between these two areas cross-fluctuation was present.

At operation (14 July 1978) a needle was inserted into the thigh and blood aspirated. It was decided then to proceed with a laparotomy at which a large pulsating haematoma on the left side of the pelvis was identified. Further examination revealed a leak in the region of the proximal end of the existing aortofemoral graft. The proximal end of the graft was therefore excised and a large defect was found involving the adjacent posterior wall of the aorta. The defect extended between the two lumbar vertebrae (*Fig.* 1) and the intervertebral disc had completely disappeared. A sleeve graft of

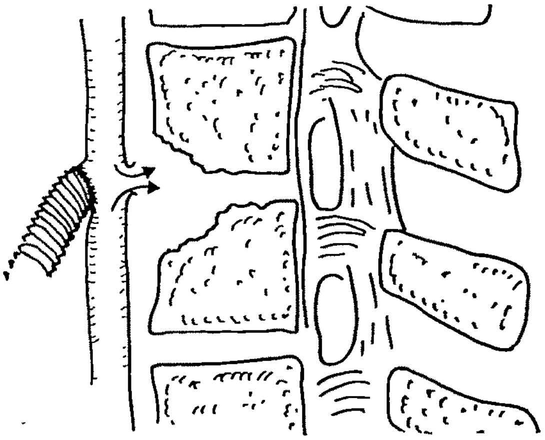

Fig. 1.

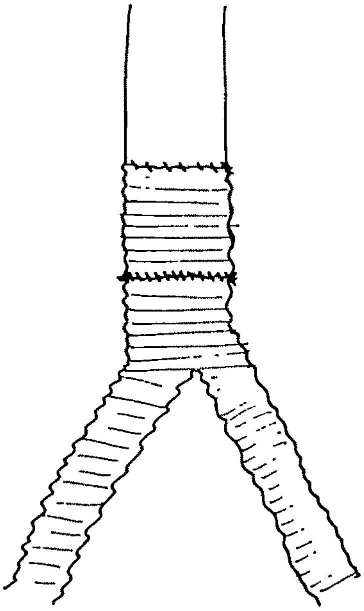

Fig. 2.

Dacron was then inserted between the proximal aorta and the distal part of the existing bypass graft (*Fig.* 2). *S. choleraesuis* was isolated from the haematoma aspirate, portions of graft and the excised aortic wall. The patient was therefore commenced postoperatively on 12 g of ampicillin with the subsequent addition of gentamicin 80 mg t.d.s. when the

drainage fluid continued to show a moderate growth of *S. choleraesuis*. This growth gradually lessened over the next 2 weeks as shown by daily culture until by 6 August 1978 three consecutive negative specimens of drainage fluid had been obtained and the drains were then removed. The patient made an excellent postoperative recovery and 4 months later remains well. He is still maintained on ampicillin 500 mg q.i.d. 6 months after operation.

Discussion

There are 23 reports available in the literature concerning salmonella infection causing rupture of an atherosclerotic abdominal aneurysm. Zak has previously emphasized the importance of recognizing this entity in patients known to have arterial aneurysms who subsequently develop salmonella infections, as well as in patients with salmonellosis who die in irreversible shock (Zak et al., 1958).

This case is the first of its kind in which infection has occurred in association with a prosthetic Dacron graft. The commonest salmonella affecting the Australian population, according to the Australian Communicable Diseases Intelligence 1978 (nos. 18, 3 and 8), is *S. typhimurium*, with no overall preponderance of any other serotype. At our own hospital from January 1977 to November 1978 65 cases of salmonellosis have been identified. Of these, 48 (74 per cent) were cases of *S. typhimurium*. Our patient was the only case of *S. choleraesuis* identified during this period. This strain, although it is not a common cause of salmonella infection, accounts for 8 out of the 23 reported cases of aorto-endovasculitis, i.e. an incidence of 33 per cent.

If invasion from the gastrointestinal tract occurs, septicaemia, multiple abscess, osteomyelitis and aortitis can develop. Patients especially at risk of developing systemic disease are those with sickle cell anaemia (Hand and King, 1978) or gastrointestinal carcinoma (Youmans et al., 1978).

There are two possible mechanisms which could have operated in our cases. Infection may have developed in the arterial wall following septicaemia with subsequent rupture and vertebral erosion. Alternatively, there may have been a direct extension from the adjoining lumbar vertebrae following a lumbar osteomyelitis causing rupture of the arterial wall. The symptom sequence, however, suggests the former.

On reviewing the literature, the commonest symptoms of this condition are fever, abdominal pain and back pain. Positive blood culture was present in 19 cases and there was an associated osteomyelitis of the lumbar vertebrae in 8 of these. Including our own, 24 cases have been reported (*Table I*): 14 of them were diagnosed at post-mortem; 9 patients underwent an attempted surgical repair, but only 4 of the patients have survived surgery. To the best of our knowledge this is the first reported case involving a synthetic graft. This case is presented because it emphasizes several important points. In only 10 of the 24 reported patients was the cause diagnosed before death. *S. choleraesuis* is the salmonella most often associated with infection of diseased blood vessels and should be suspected in patients with known arterial disease who become shocked after salmonella infection, especially if this shock is unresponsive to conventional measures.

Finally, because of the infrequency of this disease, there are no established guidelines to indicate how long the patient should be maintained on ampicillin. Experience with treatment of carriers has shown successful eradication with 3 months' therapy (Garrard and Lambert, 1973). However, the well-known persistence of these organisms in the tissues with subsequent relapse and the presence of a synthetic graft makes the decision about when to cease medication difficult.

Emergency treatment of variceal haemorrhage*

S. SAGAR, I. D. HARRISON, R. BREARLEY AND R. SHIELDS†

SUMMARY

For the initial control of haemorrhage from oesophageal varices, two methods of vasopressin administration have been compared—the conventional bolus of 20 units and a low dose infusion of 0·4 units per minute.

Twenty patients bleeding from oesophageal varices, confirmed by endoscopy, were allocated into either treatment group (10 in each). Vasopressin infusion stopped bleeding in 86 per cent of the episodes in contrast to 12·5 per cent ($P<0{\cdot}01$) with bolus doses. Balloon tamponade with a Sengstaken-Blakemore tube was used to control bleeding in only 2 episodes in patients on infusion and in 10 episodes in patients on bolus doses of vasopressin ($P<0{\cdot}05$). Our study confirms that low dose vasopressin infusion is more effective in controlling bleeding from oesophageal varices than conventional bolus doses.

In cirrhotic patients, bleeding from oesophageal varices is a critical event. About half of those patients admitted to hospital die (Rothwell-Jackson and Hunt, 1971; George et al., 1973). The rapid control of massive bleeding constitutes the major initial challenge in the emergency treatment of such patients. Despite encouraging reports (Orloff et al., 1975), emergency portasystemic shunts are followed by an unacceptably high morbidity and mortality rate. Direct occlusion of the varices by operations such as oesophageal or gastric transection carries a considerable postoperative mortality (in our hands 50 per cent overall and 90 per cent in Child's (1964) group C). Therefore, we, with others, are seeking to develop simpler, non-operative measures to control bleeding from varices.

The initial treatment of these patients is usually the intravenous administration of vasopressin. We decided to determine whether *continuous infusion* was more effective than the more conventional repeated *bolus* injections.

Patients and methods

Over a 2-year period (June 1976 to May 1978), 20 patients who were admitted to the Professorial Unit, Liverpool Royal Infirmary, with active bleeding from varices were considered suitable for vasopressin treatment. All these patients were emergency admissions, either coming directly into our unit or being transferred from other hospitals after massive haemorrhages. Bleeding from varices was confirmed by endoscopy and/or barium studies within 24 h of admission.

During the first 12 months (June 1976 to May 1977) of this study all patients were treated with repeated bolus intravenous injections of vasopressin (bolus group, $n = 10$). Doses of 20 units diluted in 100 ml dextrose 5 per cent w/v solution were injected over a period of 20 min and repeated at intervals of 2–4 h until the bleeding stopped. In the second year (June 1977 to May 1978) the patients were treated with a continuous infusion of vasopressin (infusion group, $n = 10$). Vasopressin (200 units) was diluted in 500 ml dextrose 5 per cent w/v solution and infused at a rate of 0·4 units/min. This low rate of infusion was achieved using an IVAC pump. When bleeding was controlled and vital signs stabilized, infusion was gradually decreased and stopped within the next 12 h.

The initial general resuscitation of all patients with bleeding varices admitted to our unit is standard and includes replacement of blood, fluid and electrolytes, the correction of coagulation defects and continuous nasogastric aspiration (Shields, 1977). All patients were monitored for pulse rate, blood pressure and central venous pressure changes and with continuous electrocardiography.

There were 16 episodes of bleeding treated with bolus vasopressin and 15 with continuous infusion. Treatment was regarded as successful if bleeding was stopped and no further haemorrhage occurred within 24 h of cessation of vasopressin. If bleeding persisted or recurred within 24 h, our policy was to use balloon tamponade with a Sengstaken-Blakemore tube to control haemorrhage. Hence, another index of success or failure of vasopressin treatment was the frequency of balloon tamponade.

Results

Comparability of groups

The two groups of patients were well matched for numbers, age, sex (*Table I*), assessment of liver function (Child, 1964) and the aetiology of cirrhosis (*Table II*). The diagnosis of cirrhosis was confirmed on subsequent histology. The majority of the patients had alcoholic cirrhosis—7 of the 10 patients in the bolus group and 9 of the 10 in the infusion group. One patient in each group had primary biliary cirrhosis, one patient in the bolus group had schistosomiasis and another portal vein thrombosis.

Table I: AGE AND SEX DISTRIBUTION IN BOTH GROUPS

Vasopressin	Mean age (yr)	Males	Females
Bolus ($n = 10$)	50·5±3·6	9	1
Infusion ($n = 10$)	53·8±2·4	8	2

Table II: CLINICAL STAGING AND AETIOLOGY OF CIRRHOSIS

	Child's classification			Aetiology of cirrhosis		
	A	B	C	Alcoholic	Primary biliary	Other
Bolus	1	5	4	7	1	2*
Infusion	—	6	4	9	1	—

* Portal vein thrombosis and schistosomiasis.

Control of bleeding

Bleeding was controlled in only 2 of the 16 episodes (12·5 per cent) when vasopressin was given in the conventional bolus doses. In contrast, using a continuous infusion of vasopressin, bleeding was stopped in 13 of the 15 episodes (86 per cent). Balloon tamponade was used on 10 occasions in 8 patients in the bolus group (*Fig.* 1*a*) and in only 1 patient (on 2 occasions) in the infusion group (*Fig.* 1*b*) ($P<0{\cdot}05\chi^2$). Emergency operations (oesophageal or gastric transection) were carried out in 7 patients to control bleeding: 6 in the bolus group and 1 in the infusion

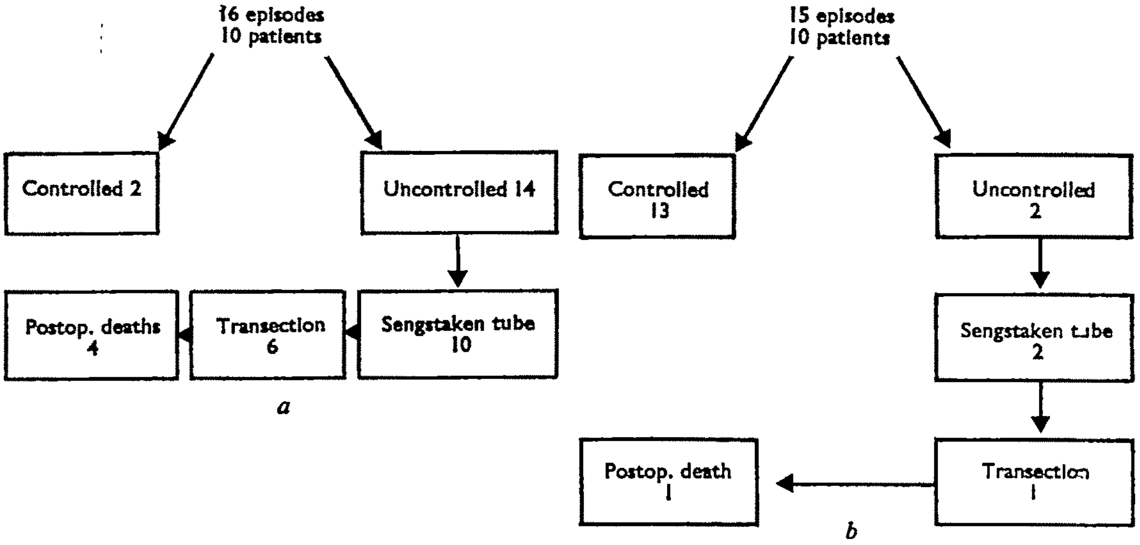

Fig. 1. Outcome of patients in (*a*) the bolus group and (*b*) the infusion group.

group. In 3 patients in the infusion group portasystemic shunt was performed as an elective procedure after necessary investigations and preparations.

Mortality

Nine patients died (45 per cent)—5 after operations, 4 due to liver failure and 1 due to massive haemorrhage (*Table III*). Three patients were found to have malignant disease—1 hepatoma in each group and 1 carcinoma of the bronchus for which no operation was carried out. One patient died after massive haemorrhage in spite of strenuous efforts at resuscitation.

Blood tranfusion requirements (*Table III*)

The amount of blood transfused per episode, estimated as units, was not significantly different between the two groups: 4·7 (±1·8 s.d.) in the bolus group and 3·8 (±0·6 s.d.) in the infusion group. However, it should be noted that many of our patients were referred from other hospitals where variable quantities of blood had been transfused so that comparison of the groups was difficult.

Discussion

Vasopressin is a powerful vasoconstrictor and its role in the management and control of bleeding oesophageal varices has been, and is still, under investigation. The report of Kehne et al. (1956) of successful control of variceal haemorrhage with intermittent and repeated intravenous injections of vasopressin is the basis of current conventional treatment. However the initial promise of this treatment was not realized, as recurrent bleeding on stopping the drug was common and systemic effects, such as coronary insufficiency, decreased cardiac output and in some cases peripheral vascular collapse, were reported (Wexler, 1977). A tachyphylactic effect with diminished vascular response was also seen with repeated bolus injection. Nusbaum and Conn (1976) showed that systemic side effects could be abolished by infusing vasopressin directly into the superior mesenteric artery. Intra-arterial vasopressin infused in low doses of 0·2 units/min reduced portal venous pressure by 50 per cent and superior mesenteric artery flow by 60 per cent.

Table III: BLOOD TRANSFUSED AND POSTOPERATIVE MORTALITY

	Blood transfused (units)	Postop. deaths
Bolus	4·7 (±1·8)	4
Infusion	3·8 (±0·6)	1

In a prospective controlled trial, Conn and his colleagues (1975), in a comparison of intra-arterial infusions and conventional bolus treatment, reported that the former was more effective in controlling haemorrhage. They also showed that, with intra-arterial infusions, blood transfusion requirements were reduced. However, the overall morbidity and mortality in the two groups and long term survival were not significantly different. In animal studies Barr et al. (1975) found no significant difference in the haemodynamic effects of selective superior mesenteric artery and intravenous infusions of vasopressin in similar concentrations. These findings were further substantiated by Kerr and colleagues (1978). A recent clinical study by Johnson et al. (1977) confirmed that intravenous infusion of vasopressin was as effective as an intra-arterial infusion of the same dose.

Our study compared the conventional bolus injections with intravenous infusion as the latter eliminates the technical problems of selective superior mesenteric artery catheterization. Our results clearly show that simple intravenous infusion of vasopressin in low doses is more effective than conventional repeated bolus doses. The biological half-life of vasopressin is 20–25 min in man (Bauman and Dingman, 1976) and the therapeutic half-life is less than 5 min (Williams, 1978). Therefore, bolus injection can at best produce only a brief reduction in portal venous pressure whilst, in contrast, a continuous infusion probably produces prolonged sustained effects.

Our management of bleeding oesophageal varices was staged: vasopressin (stage I) followed by balloon tamponade (stage II) and finally, if required, emergency operation (stage III). Progression from one stage to another indicated failure of a previous stage. In the infusion group, only one patient reached stage III, whilst in the bolus group, 8 reached stage II and 6 stage III. In these last 6 patients operative disconnection of the gastro-oesophageal varices from the portal circulation was carried out in an attempt to stop bleeding and save life.

Surgery, in such emergency circumstances, carries a high mortality (5 out of 7 in the present study) and all efforts should be made to avoid operations. Other less traumatic procedures such as sclerotherapy either directly into the varices (Terblanche, 1979) or via coronary vein catheterization (Lunderquist and Vang, 1974) could be considered. If bleeding is stopped at stage I, the patient can be assessed clinically, biochemically and radiologically and a decision made as regards future treatment. We feel that if there is good liver function and a patent portal or superior mesenteric vein, an urgent shunt gives the best prognosis.

The main criticism of our study is that the comparison of the two treatment schedules was not by a random controlled trial. Whilst it is probable that the patient population may differ from year to year, our two groups seem to be matched as regards episodes of bleeding, age, aetiology of cirrhosis and Child's classification of liver function. Recently in this context, the significance of controlled trials has been questioned, and it has been suggested that 'in conditions with a high mortality historical controls may be entirely acceptable' (Editorial, 1979).

Haematemesis in infantile hypertrophic pyloric stenosis: the source of the bleeding

LEWIS SPITZ AND GILLIAN BATCUP*

SUMMARY

Thirteen infants with haematemesis associated with hypertrophic pyloric stenosis were investigated in order to elucidate the source of bleeding. All 13 patients showed endoscopic evidence of oesophagitis, moderate in 4 and severe in 9. No significant gastric mucosal lesion was found. It was concluded that the site of the haemorrhage was the oesophageal mucosa in all 13 infants. Eleven of the patients experienced troublesome postoperative vomiting.

THE reported incidence of haematemesis, as defined by the presence of streaks of red blood or 'coffee-ground' material in the vomitus, in infants with hypertrophic pyloric stenosis varies from 0·9 to 17·5 per cent (*Table I*). The source of the haemorrhage has been assumed by most authors to be acute or chronic gastritis secondary to gastric stasis due to the pyloric obstruction (Swenson, 1969; Benson, 1971; Nixon, 1976; Cook and Rickham, 1978). Dodge (1975a) noted the necropsy finding of superficial ulceration of the oesophagus in 2 infants with pyloric stenosis in whom there was a history of bloodstained vomiting.

This study was undertaken in order to establish the site of the haemorrhage in those infants with hypertrophic pyloric stenosis who presented with a history of haematemesis or who were noted to vomit blood during preoperative preparation.

Table I: INCIDENCE OF HAEMATEMESIS IN PATIENTS WITH INFANTILE PYLORIC STENOSIS

Series	Incidence of haematemesis (%)
Terezis et al. (1959)	0·9
Miller and Friesen (1956)	2·3
Rienlander and Swenson (1952)	4
Malberg (1949)	8
Pollock et al. (1957)	13
Dodge (1975)	17·5
Cook and Rickham (1978)	17–18

Patients and methods

Of a total of 78 infants with hypertrophic pyloric stenosis treated at The Children's Hospital, Sheffield, during a 3½-year period (August 1975 to January 1979), 13 (16·7 per cent) were noted preoperatively to have haematemesis.

The routine preoperative preparation of all the infants with pyloric stenosis consisted of correction of fluid and electrolyte and acid–base imbalances, where appropriate, and gentle saline nasogastric lavage to evacuate the stomach of retained milk curds. The infants were operated upon under endotracheal anaesthesia and under the same anaesthetic an endoscopic examination of the oesophagus and stomach was carried out using an Olympus Paediatric Oesophagofibrescope, Model EP Type PA (maximum external diameter 7·2 mm) in order to ascertain the site of haemorrhage. In 9 patients a random mucosal punch biopsy was taken from the greater curvature of the stomach at a point approximately two-thirds of the distance from the gastro-oesophageal junction to the pyloric sphincter. No complications from the endoscopic procedures were encountered.

Findings on endoscopy

Endoscopically four grades of oesophageal mucosal change were recognized: grade 0, normal appearance; grade I, mild erythema of the distal third of the oesophagus only; grade II, an erythematous and friable mucous membrane; grade III, superficial ulceration of the mucosa of the distal oesophagus, in addition erythema and friability.

Of the 13 infants manifesting haematemesis, 4 were classified as having grade II oesophageal changes and 9 as having grade III lesions. Scattered punctate haemorrhages were seen in the gastric mucosal surface in 6 infants, but there was no evidence endoscopically of a diffuse mucosal lesion or of an active bleeding site in the stomach.

Histopathological findings

This formed part of a study in which gastric mucosal biopsies from 35 infants with hypertrophic pyloric stenosis were compared with 33 post-mortem sections of 'normal' stomach from age-matched control cases selected to exclude any clinical history of diarrhoea or vomiting except as a terminal event (Batcup and Spitz, 1979).

None of these 35 biopsies showed mucosal erosions or an increased inflammatory cell infiltration within the lamina propria. There was thus no histological evidence of a diffuse gastritis, although examination of such a small sample could not exclude focal erosions elsewhere in the stomach.

Although three of the biopsies from infants with haematemesis showed fresh haemorrhage into the lamina propria, similar findings were recorded in a further 15 biopsies from cases with no such history, and also in 12 of the control group. In addition, no significant mucosal deposition of haemosiderin was noted. These findings suggest that there is no direct relationship between gastric mucosal haemorrhage and the presence or absence of haematemesis.

Discussion

The results of this study of 13 infants with hypertrophic pyloric stenosis presenting with haematemesis show, contrary to general opinion, that the source of the bleeding is the oesophageal rather than the gastric mucosa. As bilious vomiting is virtually unknown in pyloric stenosis (Benson, 1969; Dodge, 1975b; Cook and Rickham, 1979) it can be safely assumed that the pathological changes seen in the oesophagus are secondary to acid–pepsin reflux.

Incompetence of the lower oesophageal sphincter has been previously recorded by many authors, notably Forshall (1955) and Roviralta (1967). Pellerin et al. (1974) demonstrated reflux radiologically in 13 per cent of 627 infants with pyloric stenosis. In an unselected consecutive study of 72 infants with pyloric stenosis the incidence of oesophagitis was found on endoscopic examination to be as high as 30 per cent (Spitz, 1979).

Punctate haemorrhages in the mucosal surface of the stomach were noted in 6 of the 13 infants. No active bleeding site in the stomach could be seen in any of these patients and the presence of punctate haemorrhages did not correlate with the severity of the haematemesis. The role of the nasogastric tube in the pathogenesis of the haemorrhages is unknown, but it is of interest to note that similar lesions were noted in 20 per cent of infants with uncomplicated pyloric stenosis. This observation, together with the results of the histopathological study of mucosal punch biopsies, would tend to support the view that gastric mucosal lesions are not normally associated with pyloric stenosis. Frank ulceration of the stomach has, however, been reported in an infant with pyloric stenosis (Kelsey et al., 1968).

---

* Departments of Paediatric Surgery and Pathology, The Children's Hospital, Western Bank, Sheffield.

The clinical significance of the haematemesis in pyloric stenosis was stressed by Haberer as long ago as 1932. He noted that infants showing blood in their vomitus preoperatively were more likely to experience troublesome postoperative vomiting. This observation was substantiated in this series of 13 patients, 11 of whom experienced significant vomiting in the postoperative period.

Correspondence

Phlegmasia caerulea dolens

Sir

I was disturbed by the conclusion to which the authors of the paper 'The role of thrombolytic therapy in the management of phlegmasia caerulea dolens' (M. S. Elliot et al., *Br. J. Surg.* 66, 422–424) came concerning the effectiveness of thrombolytic therapy in this condition. In both cases the post-treatment venogram showed occlusion of the venous tree, and it would seem to me that the authors have not demonstrated that thrombolytic therapy *per se* has been responsible for the improvement. There can be no doubt that there was improvement in these patients, but we are all aware of the development of venous collaterals in such cases even in the absence of treatment.

I do not therefore believe there are necessarily grounds for attributing this success to the use of streptokinase.

AVERIL O. MANSFIELD

2 Maryland Street
Liverpool
L1 9DE

Sir

Miss Mansfield has raised a valid argument which we cannot entirely refute as pre-treatment phlebography was not possible for technical reasons in either of the patients described. Both patients exhibited residual thrombosis of the deep venous system at phlebography 14 days after treatment. In *Case* 1 this involved the calf, popliteal and superficial femoral vein but with iliac patency and almost complete superficial vein patency. In *Case* 2 there was persistent iliofemoral thrombus but with patency of the calf axial, popliteal, superficial femoral and superficial venous system. As the antecedent clinical history of phlegmasia alba dolens was 10 and 30 days respectively, the failure of streptokinase to lyse the presumed original thrombus is not unexpected.

Both cases cited follow the common pattern described in the literature of the sudden development of caerulea dolens or venous gangrene within days or weeks of the development of an iliofemoral thrombosis; presumably reflecting further propagation of thrombus into tributary veins and the superficial venous system. It is precisely in this setting that thrombolytic therapy provides a theoretically attractive mode of treatment in its potential ability to lyse this fresh 'final insult' thrombus. Conversely, venous thrombectomy in the face of old axial vein clot can be anticipated to carry a high rate of reocclusion and cannot clear tributary and superficial vein thrombus.

The dramatic and undoubted improvement within 24 h of the institution of thrombolytic therapy in the two cases reported (in marked contrast to our previously limited experience with the treatment of this condition) has led to the cautious note of optimism reflected in our report.

We would presently reserve venous thrombectomy for patients with a short history of caerulea dolens or venous gangrene without a preceding history of alba dolens or where contraindications to thrombolytic therapy exist.

Palliation of carcinoma of the oesophagus

Sir

I write to comment on the article by N. R. Saunders on intubation techniques for palliation of carcinoma of the oesophagus ('The Celestin tube in the palliation of carcinoma of the oesophagus and cardia', *Br. J. Surg.* 66, 419–421).

It is pleasing to see yet another author confirm the now widely held view that this disease is virtually incurable. He rightly implies that the only sensible course to follow is that in pursuit of maximum palliation. However, again in concert with all of the literature I have seen, he does not define what he means by the word 'palliation'. Qualitative descriptions such as 'adequate' or 'satisfactory' do not allow us to compare modes of treatment in oesophageal obstruction. This is especially troubling because almost all therapeutic manoeuvres in this distressing syndrome are fraught with morbidity and considerable mortality.

I believe it is essential to quantitate accurately palliative results by prospective study of the various treatments of oesophageal obstruction. To that end, I would draw your attention to my own work on this problem (Carcinoma of the esophagus—a new proposal for the evaluation of treatment', Stoller J. L., Samer K. J., Toppin D. I. et al. (1977) *Can. J. Surg.* 20, 454–459) in which I proposed a grade score system for the measurement of palliation. At present I am carrying out a study of palliative results in patients treated by all modes of therapy at the Cancer Control Agency of British Columbia, using the grade score system I outlined. It is my hope that, within a year or two, I will have enough data to be able to report accurately on just what happens to patients after various types of treatments in various stages of the disease.

Although lacking accurate data I must say that like many others I am thoroughly disenchanted with endo-oesophageal intubation, mainly because patients can rarely swallow anything more than blenderized food and suffer intolerable reflux. It is hard to justify a procedure with a 30 per cent inhospital mortality, which gives such poor palliation and after which the survival period is so short. My own preference at this time is for more modern types of bypass procedure, which by my own scoring system appear to be giving excellent palliation and have a much lower morbidity and mortality than that quoted by Dr Saunders. At present, however, case numbers and follow-up are not adequate for publication purposes.

Left renal vein ligation

Sir

In their article 'Left renal vein ligation in surgery for abdominal aortic aneurysm' (*Br. J. Surg.* 66, 432), Fox and Taylor report their experience of left renal vein ligation. I would like to write and support their view that it proves to be innocuous and to draw their attention to the fact that this is so even when the renal artery has to be reimplanted for surgery on aneurysms involving the renal arteries. I have had personal experience with two such cases which were reported in the *West Indian Medical Journal* (1977), 26, 34. Both cases had ligation of the renal vein with reimplantation of the artery with 60 min of warm ischaemia, with full recovery of renal function.

Postoperative wound infection

Sir,

I have read with interest the paper by Messrs Salem, Johnson and Devitt entitled 'Short term metronidazole therapy contrasted with povidone-iodine spray in the prevention of wound infection after appendicectomy' (*Br. J. Surg.* **66**, 430–431). It is regrettable that the authors felt they could not include a no-treatment control group in their series as the results from such a group may have helped the reader to place in perspective the observed high incidence of postoperative wound infection in the group treated with povidone-iodine.

As shown below (*Table I*), in my own controlled series involving 450 patients and three treatment groups (Gilmore and Martin, 1974) the incidence of postoperative wound infection in the control group was very similar to the incidence of infection now reported for the povidone-iodine group. Similarly, my results with povidone-iodine alone in all grades of appendicectomy closely mirror those now reported for the patients who received metronidazole prophylaxis.

Table I: INFECTION RATE RELATED TO SEVERITY OF APPENDICITIS

	Control		Povidone-iodine	
Severity	Total	Infected	Total	Infected
Normal	35	4 (11%)	37	1 (2·7%)
Inflamed	75	6 (8%)	81	2 (2·5%)
Gangrenous	26	5 (19%)	17	3 (17·6%)
Perforated	15	9 (60%)	14	6 (42·8%)

I do not accept that a significant proportion of our postoperative wounds may have been classified as sterile when they were contaminated with Bacteroides organisms since the main criteria for infection was the presence of pus. I agree that anaerobic culture techniques have improved in recent years, but we did obtain bacteriology reports from over one thousand swabs in the course of the study and we identified Bacteroides organisms from 9 appendices, 8 operative wounds and 5 postoperative wounds. In contrast, *Escherichia coli* was by far the commonest organism isolated at operation both from the appendix *in situ* (90) and from the wound prior to spraying and closure (61). It was also the organism found most frequently in the infected wounds (24). Effective prophylaxis against *E. coli* and similar organisms cannot be achieved with metronidazole whereas povidone-iodine is bactericidal against anaerobic and aerobic organisms.

It is not apparent why there should be such a variation in the demonstrated levels of efficacy of povidone-iodine prophylaxis, but what is clear is that in both series the levels of postoperative wound sepsis involving gangrenous or perforated appendices are unacceptably high. In these patients I have now adopted as a general policy the use of antibiotic cover (three doses of gentamicin and metronidazole) combined with topical prophylaxis with povidone-iodine.

In the case of normal or inflamed appendices and in other low to medium risk surgical procedures I remain convinced that topical prophylaxis with povidone-iodine dry powder spray allied to good surgical technique will minimize the incidence of postoperative wound sepsis without the risk of resistant organisms developing. This policy allows agents such as metronidazole and the aminoglycosides to be kept in reserve for use in high risk situations where they may prove invaluable.

Book reviews

Scientific Basis of Gastroenterology

Edited H. L. Duthie and K. G. Wormsley. 240 × 160 mm. Pp. 498+x. Illustrated. 1978. Edinburgh: Churchill Livingstone. £17·00.

This book aims to present to clinicians the basic science involved in understanding the derangements of gastro-enterological diseases. A team of expert and respected contributors has been assembled, mostly from the British Isles but including some from Europe, Australia and America. The presentation is good, the quality of paper being reasonable and the print clear.

The first section of the book, entitled 'Basic Principles', has chapters on gastrointestinal cell population kinetics, vasculature, immunology and hormones. These are well-written expositions of complicated topics and will be much appreciated by the non-specialist. There follow sections on secretion, absorption and motility, with 3–6 chapters in each section.

While there is naturally some variation in the structure of different chapters, they usually include not only the scientific basis but also some discussion on how this knowledge can be applied in clinical practice.

This book, at a price that must perforce be considered reasonable by modern standards, should find its way on to the bookshelves of many clinical gastroenterologists.

MICHAEL HOBSLEY

Chirurgie '78

Edited J. Patel. 240 × 160 mm. Pp. 195. Illustrated. 1978. Paris: Masson. No price given.

Chirurgie '78 is a résumé of the round-table conferences, forums and papers from the 80th French Congress of Surgery held in Paris in September 1978. It covers all aspects of surgery, including orthopaedic and vascular surgery.

There are good reviews of pancreaticoduodenectomy for chronic pancreatitis and preoperative assessment of jaundice. The emphasis is mainly gastrointestinal, but there is a useful round-table discussion on whether patients are being overtransfused and whether one can reduce the demands on blood transfusion units. Equally there is a timely review on intravenous feeding before and after surgery. Altogether the book provides a very good insight into current French surgical thought.

J.-C. GAZET

Why Not Say It Clearly? A Guide to Scientific Writing

Lester S. King. 210 × 135 mm. Pp. 186. 1978. Boston: Little, Brown. $5.95.

Complaints about the indifferent standard of medical and scientific writing date back to the founding of the Royal Society. Concern about the ability of the contemporary doctor to write clearly is continuously voiced. Recently, several short texts have been written to aid the prospective writer. This book has been written by the former senior editor of the *Journal of the American Medical Association*; the content is drawn from his experience as an editor of many years' standing and from his participation in courses on writing scientific English clearly. The depth of experience is apparent throughout the book, yet the author does not lose contact with his reader. Many of the points raised are those which the beginner finds so difficult, and his suggestions for dealing with the blank-page phenomenon shows understanding of the problems which the writer faces. His axiom that good writing means hard work, frustration and anguish will remind many of their feelings when faced with revising and rewriting manuscripts.

This book, together with others that introduce the technique of writing, should be available in medical libraries. At the price ($5.95) I would suggest that this book is worth buying for repeated study.

R. C. G. RUSSELL

Current Surgical Practice, Volume 2

Edited John Hadfield and Michael Hobsley. 240 × 155 mm. Pp. 378+xii. Illustrated. 1978. London: Arnold. £11·00.

This book contains twenty lectures all of which are concerned with surgical topics relevant to current practice. Each has been delivered at the Royal College of Surgeons by a surgeon actively engaged in clinical work who has written up his talk under the guidance of the editors. Each account is authoritative and clear and is supported by an adequate list of references and/or a bibliography. There has, of course, been some modification from the spoken word and this redrafting has allowed the text to be as up-to-date as possible. In some cases there has been considerable expansion but, none the less, many of the essays may be read in not much more time than an examiner would take to study an ideal answer to a question in the FRCS examination, which is one way in which they may be approached. However, it is evident that the authors, and the editors, have gone to a great deal of trouble to ensure that the quality of the coverage is such that this is also a volume which the qualified surgeon will wish to own and refer to frequently.

This is the second book presented under the seal of the Royal College of Surgeons, which is only right, for the series is excellent evidence of the College's continuing interest in raising the standards of surgical education.

JOHN MCFARLAND

Noninvasive Measurement of Regional Cerebral Blood Flow in Man

V. D. Deshmukh and J. S. Meyer. 235 × 160 mm. Pp. 238. Illustrated. 1978. London: SP Medical & Scientific Books. £14·00.

This is a small, well-produced and very expensive volume concerned completely with the non-invasive measurement of regional cerebral blood flow in man using intravenous, radioactive xenon. It represents the personal experience of two research workers in a laboratory in Baylor University, Houston, and contains an extremely detailed review of the subject, the personal work of the authors, and details of the establishment, contents and day-to-day running of their laboratory.

It does, however, unfortunately contain relatively few hard clinical facts. There are only 47 pages devoted to clinical applications of the method and even these are not supported by figures which would enable an accurate and objective assessment to be made. This book is undoubtedly essential to anyone who is interested in studying cerebral blood flow, but publication might be a little premature and may have been better postponed until the authors had a larger clinical experience which would have added greatly to its value to all surgeons interested in vascular and neuro-surgery.

C. W. JAMIESON

The Shoulder: Surgical and Non-surgical Management

Edited M. Post. 260×200 mm. Pp. 581+xii. Illustrated. 1978. London: Kimpton. £24·50.

ALTHOUGH fifteen authors have contributed to this publication, the editor has written most of it himself. The book is in the tradition of previous studies on the shoulder by Godman, by Moseley and by Bateman. Is there a place for yet another comprehensive work on the shoulder? It is, of course, only too easy for a reviewer to pass carping comment, and anyone who has not burnt the midnight oil in the laborious task of authorship should beware of superficial judgement, but what is one to say? A new book should certainly reflect recent advances, and in this respect it is a disappointment. Only a few chapters contain new material; the chapter on shoulder arthroplasty and total shoulder replacement stands almost alone in this regard. The chapter on radiological diagnosis does not do justice to recent radiological and other non-invasive diagnostic techniques. Dr Post's own 'Orthopaedic management of neuro-muscular disorders' is comprehensive and informative, although Howard's technique, reported in 1961, of thoraco-scapular fusion—undoubtedly the best mode of stabilizing the scapula in appropriate cases—is surprisingly not mentioned. It is difficult to justify the inclusion of a chapter on 'Antimicrobial therapy in orthopaedic patients' as if it differed in the shoulder from elsewhere, and somewhat surprisingly, no less than 8 pages are devoted to the management of unstable thoracic injuries. Enthusiasts are liable to stretch the boundaries of their subject, but is this not going too far?

However much a reviewer may carp, this publication is clearly a labour of love, and who would argue with Tennyson that 'tis better to have loved and lost than never to have loved at all?

LIPMAN KESSEL

Les Tumeurs Oddiennes

Professor Marchal and Professor Hureau. 240×160 mm. Pp. 180. Illustrated. 1978. Paris: Masson. No price given.

Les Tumeurs Oddiennes (ampullary tumours of Vater) by Professors Marchal and Hureau is an extensive but succinct 180-page review with 430 world-wide references quoted. It attempts to answer three questions: whether these tumours are always malignant, whether diagnosis has been improved by modern techniques, in particular endoscopy, and finally, whether these lesions should be treated by major ablative surgery or by local excision. 'Tumeurs Oddiennes' are defined as tumours of the biliary, pancreatic and duodenal junction, excluding periampullary lesions. A comparison is made between 736 French cases and 1089 from the world literature. Considering one section, where surgery was undertaken, the French series had a resectability rate of 78·7 per cent compared with 87·2 per cent in the world series. Of interest, 19·2 per cent had a papillectomy compared with only 6·6 per cent in the latter series and there was a correspondingly low mortality of 9·1 per cent compared with 19·6 per cent in the world series. Generally, pancreaticoduodenectomy had a 19·4–17·7 per cent mortality.

The chance of surviving 5 years after papillectomy was the same in both series at 30 per cent excluding operative deaths. This is considerably better than that following pancreaticoduodenectomy, at 19·4 per cent in the French series and from 6·3 to 54 per cent in the world series.

The questions of preoperative assessment, selection of cases and evaluation of postoperative problems are thoroughly discussed.

This is an extremely good monograph from the French Association of Surgery and should be read by all those interested in malignant disease of this area. It is well worth translating into English.

J.-C. GAZET

Mnemonics and Tactics in Surgery and Medicine

J. J. Shipman. 170×105 mm. Pp. 308. Illustrated. 1979. London: Lloyd-Luke. £4·50.

SOME lists of facts in medicine and surgery do not fit together in a logical and easily remembered pattern. One way of recalling them is to form mnemonics. Home-made mnemonics are best; by the time the list has been tailored to fit the chosen key word, the list is so imprinted on the memory that the key word can be forgotten. Some gems become classics and should be preserved. The very best are anatomical mnemonics and unprintable.

John Shipman's friends have for years been regaled by the latest finding, and he has now published his collection in paperback, relating to general medicine and general surgery. Also included are succinct notes on how to deal with clinical problems, and a few cartoons. The best mnemonics are short, simple, and significant. For instance, if an enlarged lymph node is detected we are reminded by the words PALS to examine the Primary site, All other glands, the Liver and Spleen. Some lists are too long, or the references are too obscure to remember, but are otherwise enjoyable. For instance, I had not previously encountered the name of my distinguished Royal Free Hospital colleague, Sheila Sherlock, as an apt mnemonic for the results of hepatic damage.

It was right that these should be recorded. I hope that John Shipman will continue to collect them for future editions, since he has become the self-appointed HAM (Honorary Archivist of Mnemonics).

R. M. KIRK

Nouveau Traité de Technique Chirurgicale: Volume 15

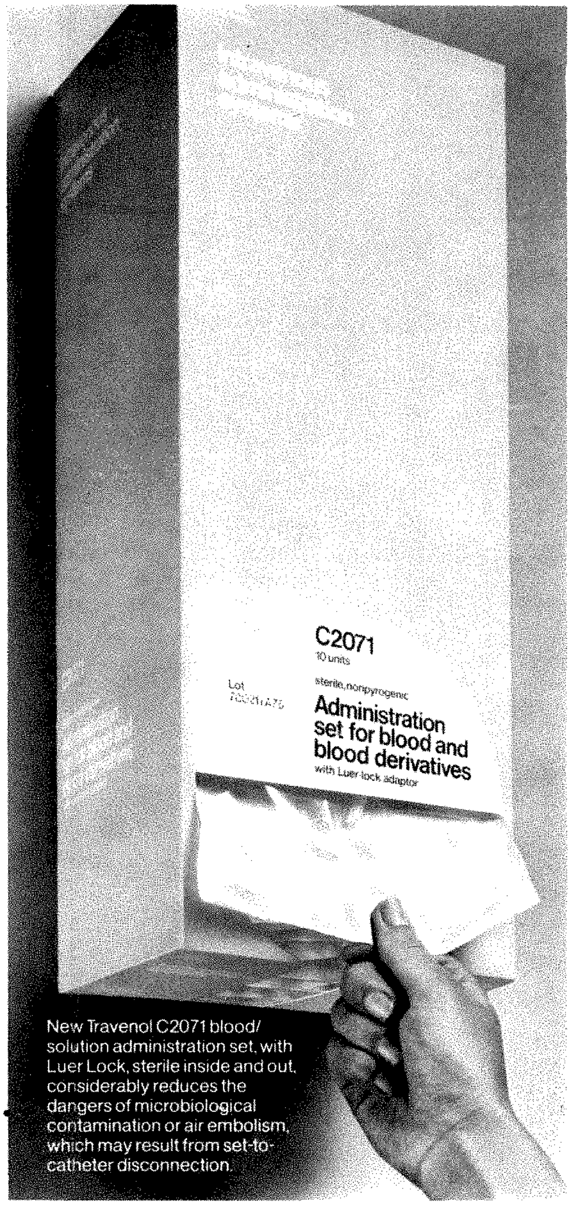
Professor Couvelaire and Professor Cukier. Second edition. 260×190 mm. Pp. 856+xiv. Illustrated. 1978. Paris: Masson. No price given.

THE *Nouveau Traité de Technique Chirurgicale* is a series in 15 volumes of French surgical technique, and in many ways is similar to British texts such as Robb and Smith, though it relies more on the written word than on illustrations. The volume reviewed here, number 15 in the series, is on urology. The contents are listed both in French and English. Each chapter deals with each organ or structure according to standard orthodox practice. The text is well illustrated with explicit, sharp, well-drawn, step-by-step figures. The text is clear, concise and carefully worded. However, it is a manual of operative surgery and, whereas all current procedures are described, it does not deal in depth with the indications for surgery or the complications. For example, renal transplantation is dealt with as a surgical exercise, not as a subject for discussion.

This is an excellent textbook, to be read in the original, but it would not fill a gap if translated as there are similar excellent texts in the English language.

J.-C. GAZET

Travenol Sets the Standards



New Travenol C2071 blood/solution administration set, with Luer Lock, sterile inside and out, considerably reduces the dangers of microbiological contamination or air embolism, which may result from set-to-catheter disconnection.

Travenol intravenous administration sets exemplify three distinct standards of excellence.

A standard for design. Each set is designed to meet a known clinical need, and exhaustively tested to ensure that it does so.

A standard for manufacture. Rigorous quality control monitors every stage of production, from selection of raw materials to final sterilization, packaging and storage.

A standard for choice. The microbiological dangers of intravenous therapy can be reduced by choosing the right set for each procedure and so avoiding unnecessary connections.

For full details of the complete range of Travenol intravenous administration sets, please contact Marketing Services Department.

Travenol choice makes intravenous therapy safer

You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you
see a staph. infection. —The ubiquitous staph.
needs an ubiquitous antibiotic—penetrating
all the tissues of the body and effective
wherever staphylococci are found.
Any staphylococcal infection
in hospital is a candidate
for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole

fucidin

FUCIDIN (sodium fusidate B.P.)
Dosage:
Adults: 500 mg (2 capsules) 3 times daily with food.
Children: 20-40 mg/kg body weight daily in 3 divided doses with food.

The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:
After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decice whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.
Product Licence No: 0043/5019.
Each capsule contains 250 mg sodium fusidate B.P.

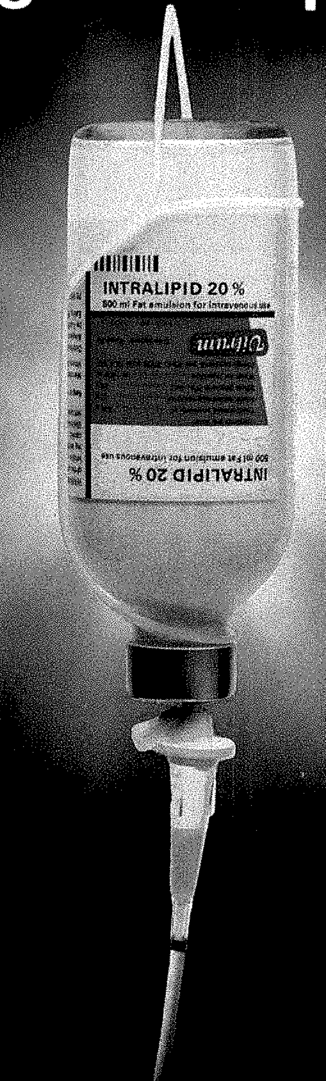
How to strengthen the post-op life line



Intralipid®

soya bean oil emulsion 10% and 20%

the most concentrated source of energy for central and peripheral infusions from the world leaders in complete intravenous nutrition

PRESCRIBING INFORMATION

INTRALIPID® 10% INTRALIPID® 20%

Presentation A milky-white oil in water emulsion

	Intralipid 10%	*Intralipid* 20%
Fractionated soya-bean oil	50 g	100 g
Fractionated egg lecithin	6 g	6 g
Diluted glycerol (Ph. Int.)	12.5 g	12.5 g
Water for injections to 500 ml		

pH c. 7. The solution is sterile and pyrogen-free.

Uses When feeding patients intravenously the possibility of providing a sufficient amount of energy in the form of carbohydrate is limited by such considerations as hypertonicity, hypervolaemia and the tendency to thrombophlebitis. The development of fat emulsions has overcome these problems. Fat has a high energy value (9.3 calories per gram) and by the use of fat emulsion it is possible to provide a high calorie intake in a relatively small fluid volume. Fat emulsions also have a protein-sparing effect when given in conjunction with amino-acid solutions to correct negative nitrogen balance. The intravenous fat emulsion Intralipid is metabolised in the same way and at the same rate as normal chylomicrons. One litre of Intralipid 10% provides 1 100 calories and 1 litre of Intralipid 20% provides 2 000 calories.

Indications Intralipid fat emulsions are indicated in conditions of severe protein depletion requiring also a high energy intake to compensate for excessive loss of calories following trauma, infection, fever, burns, etc.

Dosage and administration Intralipid 10%: 500–1 500 ml daily in conjunction with intravenous amino-acids. For increased caloric requirements Intralipid 20%: 500–1 500 ml daily in conjunction with amino-acids. Intralipid 10% and 20% are administered by slow intravenous infusion. During the first 10 minutes the drip rate should be adjusted to 20 drops per minute and after half an hour this can be adjusted to a final rate of 60 drops per minute. 500 ml of either emulsion should be given in not less than three to five hours on the first day of infusion. On the first day of infusion it is advisable to administer 10 ml Intralipid 10% or 5 ml Intralipid 20% per kg body weight. Subsequently the dose is usually doubled, and when a larger intake is indicated it may be increased to 3 g fat per kg body weight.

Infant dosage Intralipid 10% or 20%: 15–20 ml per kg body weight in 24 hours.

Contra-indications, warnings, etc. Intralipid is contra-indicated in pathological hyperlipaemia and severe liver damage.

Precautions When daily intravenous fat administration for more than one week is indicated it must be ascertained, in order to prevent the development of cumulative lipaemia, that the patient is capable of eliminating the infused fat from the circulation, and this function can be tested in the following manner. In the morning following the first day's infusion, a citrated blood sample is drawn, preferably when the patient is still in a fasting state. The blood sample is centrifuged at 1 200–1 500 rpm. If the plasma is then strongly opalescent or milky further infusion should be postponed. In the great majority of cases, plasma is completely clear 12 hours after the conclusion of an infusion of 2 g fat per kg body weight (corresponding to 20 ml of Intralipid 10% or 10 ml of Intralipid 20% per kg body weight). This test should be repeated at weekly intervals.

Pharmaceutical precautions Store at a temperature between 4°C and 8°C, and do not use after the date of expiry indicated. The contents of each bottle are for a single infusion and any residual emulsion should be discarded. No drugs should be added to Intralipid prior to or during infusion.

Legal category No legal restrictions on sale or supply.

Package quantities Intralipid 10%: 100 ml and 500 ml. Intralipid 20%: 100 ml and 500 ml.

Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

Manuscripts

The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

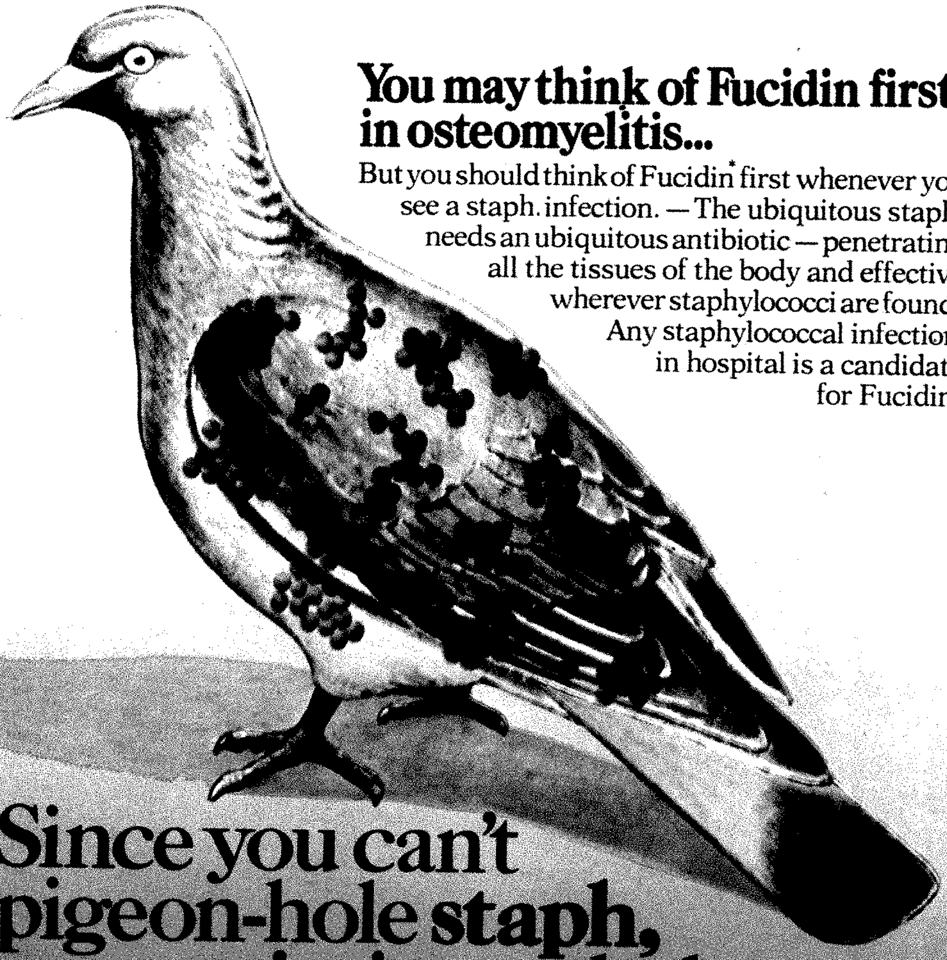
Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. The abstract must be complete in itself, outlining the aim, results and conclusions of the paper. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations

It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978; **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors.* London, Pitman, 1978.

References

In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus*. Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).



You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. — The ubiquitous staph. needs an ubiquitous antibiotic — penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole fucidin

FUCIDIN (sodium fusidate B.P.)
Dosage:
Adults: 500 mg (2 capsules) 3 times daily with food.
Children: 20-40 mg/kg body weight daily in 3 divided doses with food.
The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:
After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.
Product Licence No: 0043/5019.
Each capsule contains 250 mg sodium fusidate B.P.

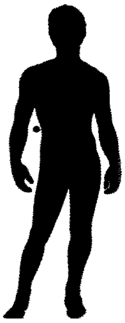
[illegible]
[illegible]
a [illegible]
complication

It has been estimated that 50% of all patients in hospital show signs of malnutrition[1,2]. Since protein calorie malnutrition is shown to impede wound healing[3] and diminish resistance to infection[4], the provision of nutritional support should be a routine consideration for all severely ill patients. When gastro-intestinal function is impaired or absent, such support must be given intravenously. And for these cases Travenol has the sensible answer: an integrated, effective, parenteral nutrition system. It includes Synthamin amino acid solutions. Non-protein calorie sources. Electrolytes. Peripheral and central venous catheters. Specially designed sets. And 3-litre Viaflex® containers for the sterile compounding of regimens in the pharmacy and their non-air-dependent administration on the ward.

Travenol has a sensible answer to parenteral nutrition – because Travenol thinks things through.



Travenol makes sense of Parenteral Nutrition

Synthamin

Presentation
Synthamin injections are sterile, non-pyrogenic solutions of essential and non-essential L-amino acids, provided with or without electrolytes. Synthamin 7S also provides calories as Sorbitol.
Indications
Parenteral nutrition.
Administration and Dosage
For intravenous administration.
An associated source of non-protein energy should be administered of not less than 0.75MJ (180 Cal.) per gram of nitrogen administered. Dosage depends on patient's metabolic requirements and clinical response.
Contra-indications
Severe liver disease. Solutions with electrolytes are contra-indicated in renal failure.
Precautions
As with all hypertonic solutions, vein irritation may occur.
Do not administer unless the solution is clear and container is undamaged.
Availability
Synthamin 7S (PL 0116/0043) 500ml £4.83.
Synthamin 9 (PL 0116/0054) 500ml £6.00.
Synthamin 9 without electrolytes (PL 0116/0067) 500ml £5.65.
Synthamin 14 (PL 0116/0055) 500ml £8.00.
Synthamin 14 without electrolytes (PL 0116/0068) 500ml £7.65.
Synthamin 17 (PL 0116/0056) 500ml £9.80.
Synthamin 17 without electrolytes (PL 0116/0069) 500ml £9.45.

A new generation of Micra Titanium Instruments.

Downs Surgical's new range of Micra titanium forceps offers advances in design and quality with a complete choice of delicate tips.
This new generation of Micra titanium forceps incorporates the requests for improvement revealed in a world-wide survey of Micra Instrument users.
Now these improvements are made possible due to our improved titanium technology.
Straight, curved and colibri forceps are available with tying platforms on tying, notched and toothed tips or as plain forceps.

For full details just return the coupon.

CHOLELITHIASIS

CHENDOL is an important addition to the Surgeon's armamentarium.

CHENDOL could be especially useful when:

1. Waiting lists are too long.
2. The patient is a surgical risk.
3. The patient is over anxious about an operation.

INDICATIONS
For the dissolution of radiolucent cholesterol-rich gallstones in functioning gallbladders. Cholesterol stones coated with calcium or stones composed of bile pigments are not dissolved by chenodeoxycholic acid.

DOSAGE
The present clinical evidence suggests that optimum results will be obtained on a dose level of 10-15 mgs per kg. body weight daily, either as a single night time dose or in divided doses.

CONTRAINDICATIONS, WARNINGS, ETC.
CHENDOL should not be administered to patients with radio-opaque calcified gallstones nor to patients with non functioning gallbladders.

CHENDOL should not be administered to women who may become pregnant, nor to patients with chronic liver disease, nor with inflammatory diseases of the small intestine and colon.

CHENDOL is generally well tolerated, the only side effects reported to date are diarrhoea and pruritus.

It has been found that after a slight reduction in dose for a few days, diarrhoea ceases and the dose can then gradually be increased to the former level. The clinician's discretion should be applied to the necessity, in individual cases, for laboratory monitoring.

Each **CHENDOL** capsule contains 125 mg chenodeoxycholic acid.

Available in securitainers of
100 capsules–N.H.S. cost £16.20 per pack
500 capsules–N.H.S. cost £78.00 per pack

Further information is available on request.

secure
Surgicare™ Drainage System
with integral
supporting strap

Surgicare™ System 2 saves the patient from the trauma of peeling off adhesive bags. The Stomahesive™ Flange can be left on the skin undisturbed for several days whilst the pouches are replaced as often as necessary. It makes possible a leak-free attachment of appliances to the skin thereby providing a unique degree of comfort free of irritation and soreness often associated with ordinary adhesives. Surgicare™ System 2 takes full advantage of these benefits which are particularly evident in the management or urostomies.

● The non-return valve permits easy access of urine to the lower part of the pouch and efficiently prevents the return of urine to pool in the area of the stoma thus the Stomahesive™ wafer is protected from the breakdown effects of urine and remains secure and leak-free for several days.

THIS IS A DRESSIN
INTO AN OPEN GR

Unconventional, perhaps – but just consider the disadvantages of so-called 'conventional' wound dressings.

Standard gauze packing requires skilled changing at frequent intervals – with dirty or infected wounds this can be three or more times a day.

Gauze packing provides inadequate drainage and poor air circulation: as it sticks to the newly formed tissue, it is uncomfortable, often painful to remove.

Now, consider the alternatives offered by new SILASTIC® Foam Dressing.

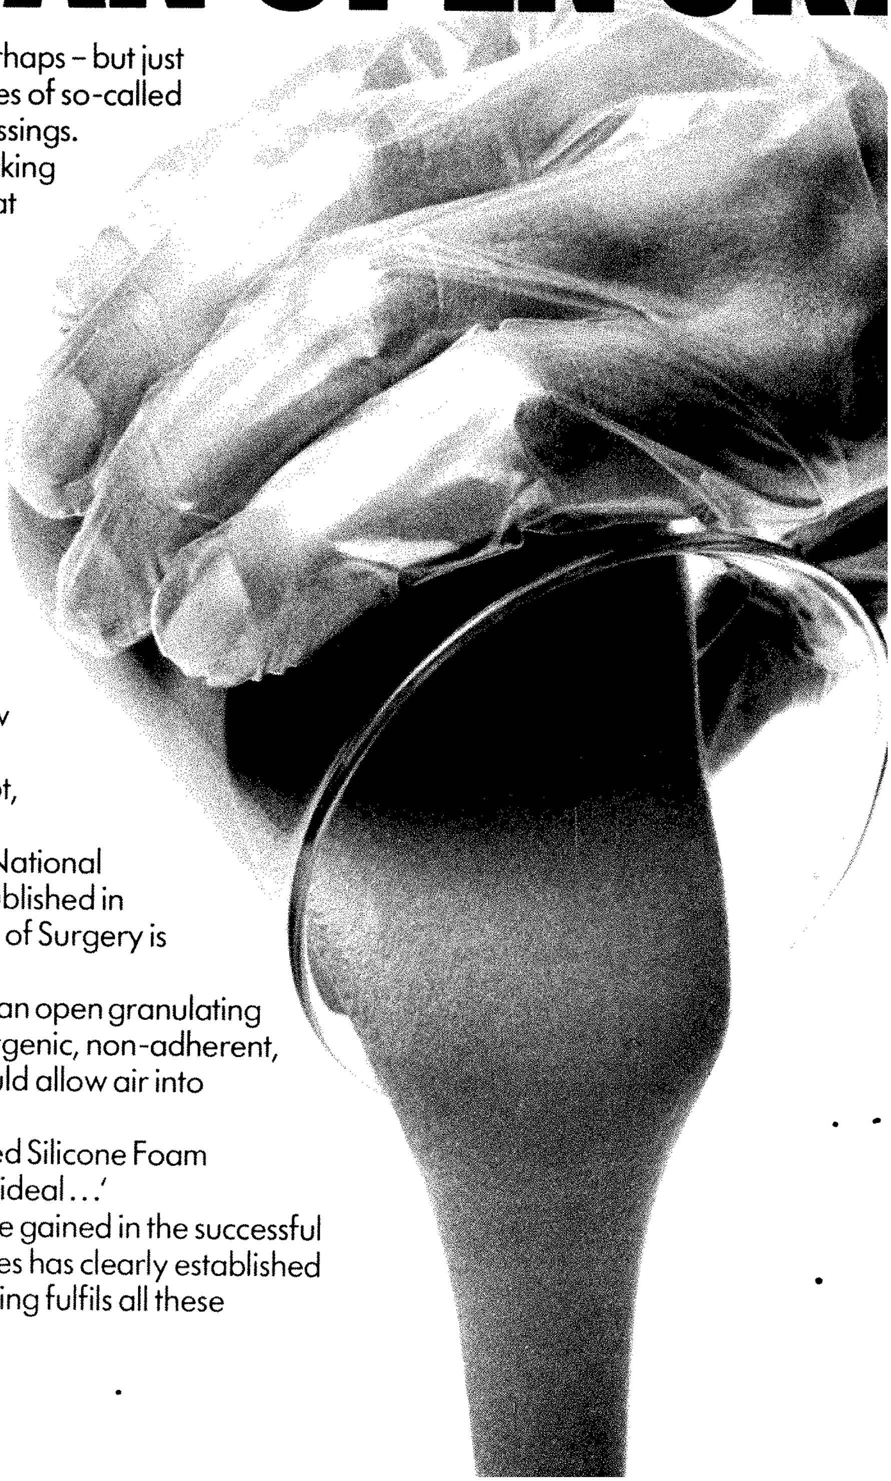
The following excerpt, from a report written by researchers at The Welsh National School of Medicine and published in 1977 by The British Journal of Surgery is of particular interest:

'An ideal dressing for an open granulating wound would be non-allergenic, non-adherent, slightly absorbent and would allow air into the wound.

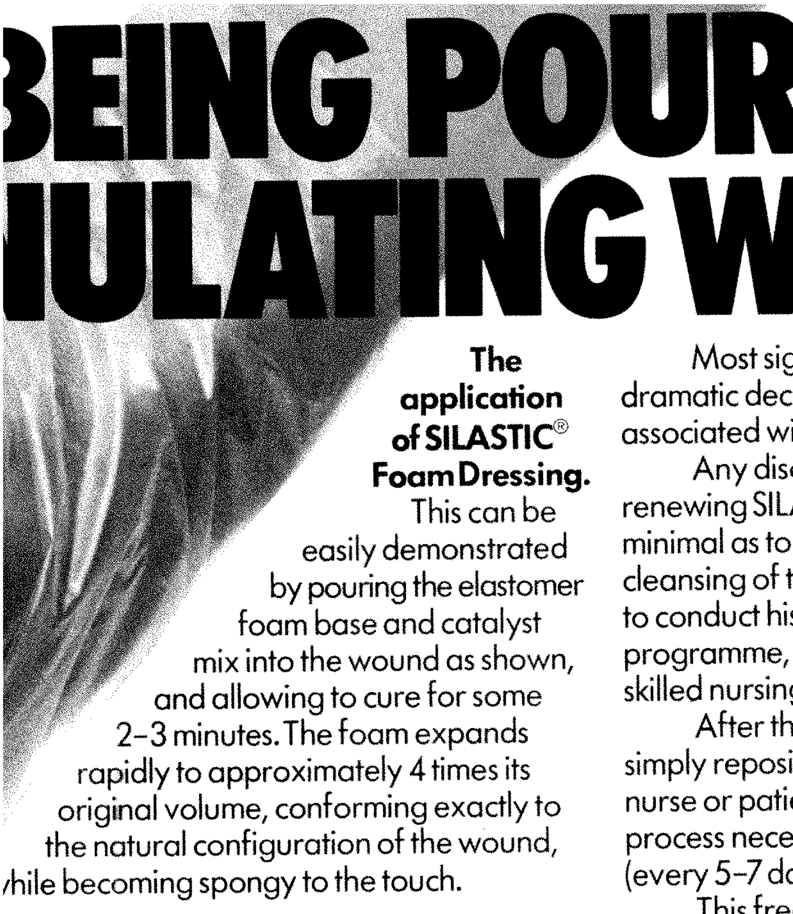
SILASTIC® Polymerised Silicone Foam Elastomer approaches this ideal...'

Since then, experience gained in the successful treatment of over 1000 cases has clearly established that SILASTIC® Foam Dressing fulfils all these requirements, and more.

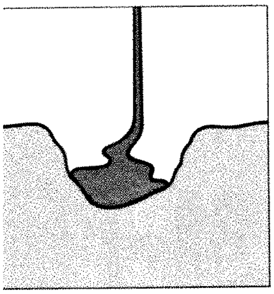
SILASTIC® is a registered trademark of Dow Corning.



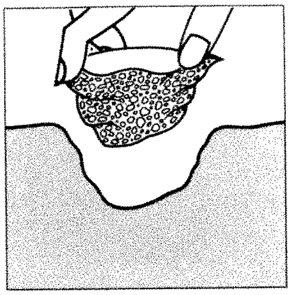
EING POURED
ULATING WOUND



The application of SILASTIC® Foam Dressing. This can be easily demonstrated by pouring the elastomer foam base and catalyst mix into the wound as shown, and allowing to cure for some 2–3 minutes. The foam expands rapidly to approximately 4 times its original volume, conforming exactly to the natural configuration of the wound, hile becoming spongy to the touch.



mply pour the Foam Dressing into
ound and allow to cure for 2–3 minutes.



The cured dressing can be removed and replaced at will.

This in itself is of considerable benefit to he patient since pressure is thus distributed nore evenly across the wound surface, with he dressing retained in place by standard, on-allergic tape for much-improved patient omfort.

Most patients are able to resume their ormal occupations much sooner after post-urgery treatment with Foam Dressing than fter treatment with conventional dressings.

Most significant of all perhaps is the dramatic decrease in patient trauma normally associated with wound dressing renewal.

Any discomfort experienced when renewing SILASTIC® Foam Dressing is so minimal as to positively encourage frequent cleansing of the wound, enabling the patient to conduct his own wound management programme, in his own home, with little or no skilled nursing attention required.

After thorough cleansing, the dressing is simply repositioned in the wound by either nurse or patient until such time as the healing process necessitates renewal of the dressing (every 5–7 days, on average).

This frequent cleansing, combined with the perfect drainage and biologically-inert construction of the dressing itself has resulted in the elimination of wound infection, a marked tendency towards faster healing and a clear advantage over conventional wound management. Cases to date include pilonidal sinus wounds, perineal wounds, conservative surgery for diabetic gangrene, sacral bed sores, abdominal wall wound breakdown and skin grafting donor sites.

Your Dow Corning representative will be glad to discuss them with you in more detail and to demonstrate new SILASTIC® Foam Dressing to you in your own office. Telephone: 0734 596888, or contact Dow Corning direct.

SURGICAL RESEARCH SOCIETY, SOCIETY OF UNIVERSITY SURGEONS AND EUROPEAN SOCIETY FOR SURGICAL RESEARCH

The Fourth Joint Meeting of the Societies took place at the Nuffield Department of Surgery, University of Oxford, on 5, 6 and 7 July 1979, with Professor H. L. Duthie (President of the Surgical Research Society) in the Chair.

Adjuvant cytotoxic liver perfusion for colorectal cancer

I. TAYLOR, J. ROWLING AND C. WEST*

SUMMARY

Colorectal liver metastases develop by malignant cells entering the portal venous circulation. A randomized prospective clinical trial was commenced in 1975 to assess the value of adjuvant umbilical vein cytotoxic perfusion (with 5-fluorouracil) following colorectal resection.

One hundred and fifty-four patients without macroscopic liver secondaries have so far entered the trial. The mean age, sex, site and stage of the disease were similar in the control and perfusion groups and there was no statistically significant difference in postoperative complications or hospital stay (17·1 ± 7·9 days control, 15·8 ± 7·4 days perfusion group).

So far, 23 deaths have occurred in the control group (20 due to recurrent disease) and 7 in the perfusion group (5 due to recurrent disease). Liver metastases were present in 13 control patients and 2 perfusion patients.

These results show an encouraging trend and suggest that adjuvant cytotoxic liver perfusion may reduce the development of colorectal liver metastases and hence improve the subsequent prognosis.

COLORECTAL cancer now accounts for approximately one-seventh of all deaths from malignant disease and is the second commonest cancer in this country. Throughout the past 25 years, despite great improvements in surgical techniques, the annual death rate has remained disappointingly high. Reported crude 5-year survival rates of all patients admitted with colorectal cancer to general hospitals have been consistently low at about 20 per cent (Slaney, 1971; Gill and Morris, 1978).

In patients seen in district general hospitals approximately 30 per cent of tumours are disseminated and incurable on admission and between 30 and 60 per cent of cases are admitted as acute emergencies (Till, 1977). Excluding these groups, the overall 5-year survival rate is still only 50 per cent (Slaney, 1971).

A prominent cause of death in patients surviving the initial surgery is the development of liver metastases. Cedermark et al. (1977) recently reported 456 patients who died of large bowel cancer and at autopsy the liver was involved with metastases in 48 per cent of cases.

Colorectal micrometastases reach the liver via the portal vein. In an attempt to reduce the subsequent development of macroscopic liver metastases a randomized trial of adjuvant cytotoxic liver perfusion given via the 'obliterated' umbilical vein during the first 7 postoperative days has been performed and patients have been followed for up to 46 months. The results of an initial pilot study have been published previously (Taylor et al., 1977).

Patients and methods

One hundred and fifty-four consecutive patients with primary adenocarcinoma of either the colon or rectum but without macroscopic liver secondaries have entered the study over the past 46 months. In the majority of cases a preoperative $^{99}Tc^m$ sulphur colloid liver scan was performed and in all patients preoperative haematological and liver function tests were carried out. More recently, ultrasound scanning of the liver has been included.

By means of the closed envelope technique 66 patients were randomly allocated preoperatively to receive adjuvant liver perfusion in addition to surgical resection. In contrast, 73 patients underwent surgical resection alone. Eleven further patients were randomized but were subsequently excluded from the study owing to the discovery of unexpected liver metastases at operation in 3, hepatic cirrhosis in 2 and because of technical difficulties in cannulating the umbilical vein in 6 patients.

Standard surgical techniques of resection were adhered to, the actual procedure to be performed being left to the discretion of the operator. In patients randomized to receive adjuvant perfusion the umbilical vein was dissected from the falciform ligament and cannulated as previously described (Kessler and Zimmon, 1967; Lavoire et al., 1967; Mann et al., 1974; Taylor et al., 1977). One gramme of 5-fluorouracil was given in 5 per cent dextrose daily by continuous perfusion for the first 7 postoperative days. Heparin (5000 u/d) was

added to the perfusate primarily to discourage portal vein thrombosis.

Postoperative blood counts and liver function tests were performed on alternate days for the first 10 postoperative days. A portal venogram was performed during the first 48 h to ensure that the catheter was well positioned and was perfusing equally both main portal branches. If not, the catheter was manipulated under the image intensifier until adequate perfusion was achieved.

The operative specimens were examined and the growths classified according to Dukes' categorization (A, B, C) of the extent of spread. The degree of differentiation was also noted.

The patients were seen at monthly intervals in the outpatient department for the first 3 months and then at 3-monthly intervals for 1 year. They were then assessed at 6-monthly intervals.

Liver function tests, ^{99}Tc^{m} sulphur colloid liver scans and, more recently, ultrasound scanning of the liver were repeated at intervals.

Results

Age and sex

The mean age of the patients in the control group was 64·4 ± 10·1 years and that of patients in the perfusion group was 63·4 ± 11·1 years. There were 44 males in the control group and 34 in the perfusion group.

Site and stage

The site and stage of each tumour are shown in *Table I*. Because of the relatively small numbers of patients, the groups have been divided into colonic and rectal (including rectosigmoid) tumours. There was no statistically significant difference between the Dukes' categorization of the tumour in each group ($\chi^2 = 0·0617$, d.f. = 2, $P = 0·96$).

There was no statistically significant difference in the degree of differentiation of the tumours in the two groups (*Table I*).

The surgeon's subjective impression of the degree of local infiltration was recorded. The tumour was mobile in 27 controls and 24 perfusion patients, moderately attached in 19 controls and 12 perfusion patients and fixed with probably macroscopic tumour remaining in 21 control and 24 perfusion patients.

Postoperative morbidity

Twenty-three patients (30 per cent) in the control group and 18 (28 per cent) in the perfusion group developed a wound infection. The chief organisms were *Escherichia coli* and bacteroides. Anastomotic leaks occurred in 7 controls and 3 perfusion patients (*Table II*).

One patient developed partial alopecia and 2 others had transient oral ulceration during perfusion. The mean postoperative hospital stay was 17·1 ± 7·9 days in the control group and 15·8 ± 7·4 days in the perfusion group. These differences were not statistically significant.

Postoperative mortality

In the immediate postoperative period there were 10 deaths: 5 in the control and 5 in the perfusion group. Necropsy was carried out in all cases. The cause of death in each patient is shown in *Table III*. It was considered that the cytotoxic perfusion was a contributory factor in 1 patient. This 65-year-old woman had a large carcinoma of the rectum surrounded by an abscess cavity. Abdominoperineal excision was performed and she was randomized to receive cytotoxic perfusion. On the ninth postoperative day she developed extensive bronchopneumonia and Gram-negative septicaemia. At this time she had marked leucopenia and thrombocytopenia.

Laboratory investigations

Five patients developed transient leucopenia (2·3, 3·2, 1·5, 1·1 and 2·1 × 10^9/dl) and 3 transient thrombocytopenia (55, 40, 35 × 10^9/dl) during perfusion. All values returned to normal on completion of perfusion. The white cell count was statistically significantly lower between the sixth and tenth days in the perfusion group compared with the control group (*Fig.* 1). However, the values returned towards normal on completion of perfusion.

Both groups had disturbed liver function values during the first 10 postoperative days (*Fig.* 2). In all patients, the mean values for bilirubin, alkaline phosphatase, AST, ALT and LDH increased between the second and tenth postoperative days. The levels in patients undergoing perfusion were not statistically significantly different from those in the control patients except during the second postoperative day when the mean AST levels were greater in the perfusion patients (*Fig.* 2).

Follow-up
In patients so far followed up for more than 1 year (47 control, 43 perfusion) the mean period of follow-up is 25·9 ± 9·7 months in the control and 27·9 ± 10·7 months in the perfusion patients.

Twenty-three patients have died in the control group and 7 patients in the perfusion group (*Table IV*). In the control group, 5 had multiple liver metastases alone, 8 had generalized metastases as well as liver metastases and 7 had local recurrence only. One patient in the perfusion group had liver metastases alone, 1 had liver metastases as well as metastases elsewhere and 4 had local recurrence. The incidence of patients with liver metastases in the two groups (13 control, 2 perfusion) was statistically significantly different ($\chi^2 = 6{\cdot}70$, $P < 0{\cdot}01$). The incidence of local recurrence between the two groups was not statistically significantly different.

One other control and one other perfusion patient are known to have local recurrence.

Discussion

The liver contains secondary deposits in about one-third to one-half of fatal cases of colorectal malignancy (Brown and Warren, 1938; Willis, 1948; Cedermark et al., 1977). Once liver metastases have developed the prognosis is bleak. Bengmark and Hafstrom (1969) found an incidence of liver metastases at laparotomy of 24·5 per cent with a mean survival of 5·1 months. Other series have also emphasized the poor outlook in these patients (Pestana et al., 1964; Jaffe et al., 1968; Taylor, 1978). It has been estimated that as many as 50 per cent of colorectal cancers will sooner or later give rise to liver metastases (Bengmark and Hafstrom, 1969) and the survival rate seems to be the same in these patients whether a palliative resection of the colon is performed or some form of bypass procedure is carried out. This argues in favour of hepatic metastases constituting a chief factor in the survival of these patients.

A great deal of work has been carried out to determine the factors that influence the development of liver metastases. A simplistic explanation would be that tumour cells embolize into the portal venous system via the invaded mesenteric veins and enter the liver. There is evidence to support this view. Brown and Warren (1938) found venous invasion by tumour in 41 per cent of necropsy cases. In operative specimens of rectal cancer evidence of venous spread is found in approximately 17 per cent (Dukes, 1957). However, the absence of intravascular permeation of tumour cells does not exclude the possibility of venous spread since malignant emboli may have been discharged into the blood stream, leaving no trace behind them.

Fisher and Turnbull (1955) recovered tumour cells from the blood of major mesenteric venous channels in 32 per cent of cases of colorectal carcinoma at surgery. They suggested that manipulation of the

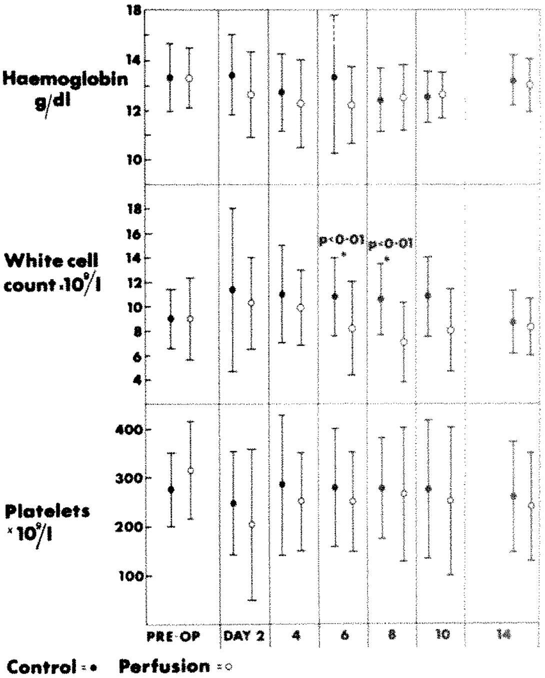

Fig. 1. Haematological investigations during the postoperative period in each group.

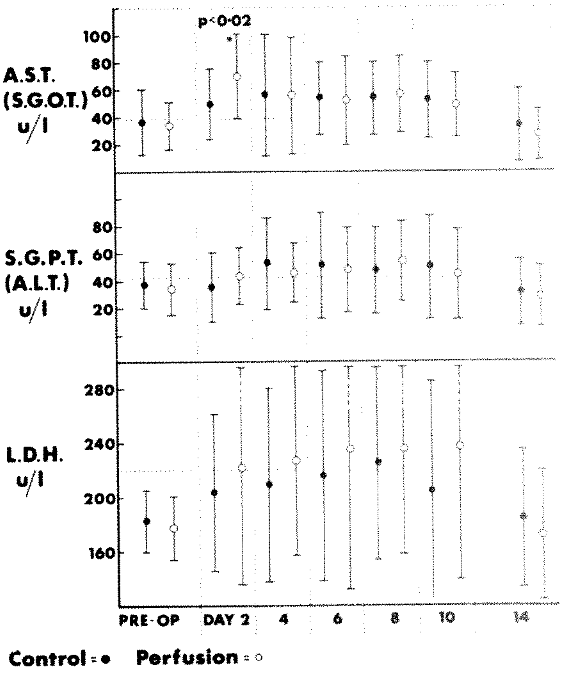

Fig. 2. Liver function tests during the postoperative period in each group.

neoplasms may result in venous dissemination of tumour cells. These findings have been confirmed in other studies (Engell, 1955; Pruitt et al., 1958; Roberts et al., 1958).

Nevertheless, in clinical terms, not all circulating cancer cells give rise to metastases. Several reports have shown that patients with malignant cells in the venous blood fare no worse than those without (Engell, 1955; Roberts et al., 1961; Sellwood et al., 1965). Also, there is little evidence that manipulation *per se* can increase the number of malignant cells discharged into the circulation. However, the added effect of operative stress has been shown on an experimental basis to produce an increase in the incidence of hepatic metastases by improving the chances of survival of cells and allowing them to establish growth within the liver (Buinauskas et al., 1958; Fisher and Fisher, 1959). Similarly, the induction of anaesthesia increases the incidence of circulating malignant cells (Griffiths et al., 1973).

The majority of tumour cells, however, will be destroyed and thus have no pathogenic potential. Some undoubtedly survive and remain dormant within the liver until some form of stimulus (perhaps an immunological one) activates their growth into a micrometastasis which penetrates the interstitial space. Since this stimulus is not as yet known, it seems sensible to try to prevent this dissemination or indeed destroy the cells entering the portal venous system.

Various cytotoxic agents have been utilized in an experimental situation to try to reduce the number of 'takes' of tumour. Cruz et al. (1956) showed that nitrogen mustard was effective in reducing the percentage of 'takes' of the carcinosarcoma tumour in rats when given within an hour of inoculation of cancer cells. Morales et al. (1957) suggested that the drug must be given at the time of inoculation and continued for some time after in order to achieve a significant reduction in the number of takes. Sporadic clinical reports have appeared in the literature advocating intraportal injection of cytotoxic agents at the time of surgery for colorectal cancer in an attempt to diminish the numbers of circulating tumour cells (Morales et al., 1957). Other surgeons (Turnbull, 1970) prefer a 'no-touch isolation' technique during resection and follow-up studies of 5-year survival using this technique yield impressive results.

In this study the primary aim was to assess the possible benefit of adjuvant perfusion of large doses of 5-fluorouracil into the portal venous system in reducing the incidence of liver metastases. It was hoped that preoperative screening techniques (liver function tests, liver scans and ultrasound of liver) and careful palpation of the liver at operation would ensure that patients with liver metastases at the time of initial laparotomy were excluded.

The actual method of liver perfusion through the umbilical vein was relatively simple to perform although cannulation proved technically impossible in 6 patients who were thus excluded from the study. The chief difficulty occurs in patients who have had previous upper abdominal surgery and in whom the falciform ligament has been divided. Since the liver metabolizes 5-fluorouracil, large doses could be given over 7 days with few systemic side-effects. Those that did occur, however, were troublesome—alopecia and oral ulceration. One patient with a carcinoma of the rectum and localized perirectal abscess formation developed postoperative Gram-negative septicaemia with leucopenia and thrombocytopenia. She eventually died and post-mortem showed severe bronchopneumonia with evidence of septic microemboli within the liver. It is considered that cytotoxic perfusion contributed to her death and accordingly patients with intra-abdominal sepsis are now no longer included for cytotoxic perfusion.

Apart from this single patient, the results of adjuvant liver perfusion in colorectal cancer appear encouraging. During the period of follow-up 23 patients have died in the control group compared with 7 in the perfusion group. Thirteen of the control patients have developed multiple liver metastases compared with 2 patients in the perfusion group. It is apparent that patients with Dukes' C lesions were particularly benefited. Forty-seven patients with Dukes' C lesions were included in the study and 22 have died during the period of follow-up—17 in the control group and 5 in the perfusion group.

Although the results are superficially promising, the period of follow-up is still relatively short and the number of patients too small to make accurate statistical conclusions. There is evidence that the incidence of liver metastases is reduced during the first few postoperative years although it is unlikely that the incidence of either local recurrence or peritoneal metastases will be materially reduced in the long term. However, it is feasible that this technique could be combined with others, e.g. adjuvant radiotherapy or immunotherapy, to reduce these sequelae.

Finally, it should be mentioned that heparin was initially included in the perfusion to discourage portal vein thrombosis but conceivably it could have a separate action in preventing the deposition of a fibrin clot around micrometastases (Hilgard et al., 1972). Other workers have shown that heparin may well have a valuable role to play in the prevention of liver metastases (White et al., 1976). This trial will not distinguish between the actions of 5-fluorouracil and those of heparin alone.

A comparative randomized trial of heparin versus streptokinase in the treatment of acute proximal venous thrombosis: an interim report of a prospective trial

M. S. ELLIOT, E. J. IMMELMAN, P. JEFFERY, S. R. BENATAR,
M. R. FUNSTON, J. A. SMITH, B. J. SHEPSTONE, A. D. FERGUSON, P. JACOBS,
W. WALKER AND J. H. LOUW*

SUMMARY

A controlled, prospective study comparing streptokinase and heparin treatment has been completed in 51 patients presenting with acute proximal venous thrombosis of less than 8 days' clinical duration. Patients were studied by means of pre-treatment, post-treatment, 3- and 12-monthly phlebography and pulmonary perfusion scanning and were followed up at 3-monthly intervals.

Of the 26 patients randomized to receive streptokinase, therapy was stopped in 3 because of complications. Phlebography 5 days after starting treatment showed 80–100 per cent lysis in 17 of the 23 patients who completed the course of streptokinase. Two patients later developed partial rethrombosis. One patient developed an asymptomatic pulmonary embolus during treatment. During follow-up (mean 19 months) only 1 of the 17 patients with 80–100 per cent lysis developed postphlebitic symptoms, 3 patients died of unrelated causes and 1 patient was lost to follow-up.

In patients randomized to heparin therapy no significant lysis was achieved in any of the 25 patients and only 2 of these patients were found to have asymptomatic legs on follow-up. Two patients in this group died and autopsy confirmed massive pulmonary embolus during treatment.

These data suggest that streptokinase is superior to heparin in the treatment of acute proximal venous thrombosis of less than 1 week's clinical duration especially if the thrombus is largely non-occlusive. It must be stressed that in order to avoid the bleeding complications of thrombolytic therapy, streptokinase must not be used within 10 days of major surgery, or even longer after vascular, neurosurgical or eye operations.

THE management of deep venous thrombosis and its complications remains a controversial problem. Pulmonary embolism represents one of the leading causes of death in hospital and nearly all patients with symptomatic iliofemoral thrombosis will eventually develop the postphlebitic syndrome characterized by oedema, eczema, ulceration and occasionally venous claudication (Bauer, 1942).

The goal of therapy in the treatment of acute deep venous thrombosis is the prevention of pulmonary embolism, the dissolution of all thrombus and the preservation of the venous valves, thus preventing subsequent ambulatory venous hypertension. Heparin appears to be of benefit in reducing the incidence of embolism (Barritt and Jordan, 1960), but it appears to be of little value in reducing the incidence of the postphlebitic syndrome.

The operation of venous thrombectomy for the treatment of iliofemoral thrombosis was first described by Leriche in 1928. Haller (1961) and Mavor (1969) demonstrated encouraging results, but long term follow-up (Lansing and Davis, 1968; Johansson et al., 1973) has shown that the incidence of the postphlebitic syndrome is not reduced, that there is a high incidence of reocclusion and that the procedure is associated with a significant morbidity and mortality.

During the past decade several reports describing the use of thrombolytic therapy for the treatment of deep venous thrombosis have been published (Kakkar et al., 1969; Tsapogas et al., 1973; Porter et al., 1975; Arnesen et al., 1978). Common to all is the significant lysis obtained in patients treated with streptokinase; however, little information is available regarding the incidence of long term rethrombosis, morbidity and incidence of pulmonary embolism during treatment. For this reason it was decided to mount a prospective, controlled, randomized, comparative study to compare conventional full dose heparin and streptokinase (Kabikinase—manufacturer's recommended dosage) in the treatment of acute deep venous thrombosis.

Patients and methods

Patients with a clinical history of deep venous thrombosis of less than 8 days' duration were submitted to bilateral ascending phlebography. If this revealed extensive proximal vein thrombosis (extension beyond the axial veins of the calf or forearm) and there was no contraindication to thrombolytic therapy, these patients were eligible for entry into the study and were randomized at this stage to one of the two forms of therapy.

Contraindications to thrombolytic therapy (and hence entry into the study) included any surgery within 7 days (neurosurgical operations within 2 months), pregnancy, menstruation, haemorrhagic diatheses, diastolic blood pressure of 110 mmHg, suspected or known bleeding lesions, a cerebrovascular accident within the preceding 6 months, a recent streptococcal infection, previous streptokinase therapy within 6 months and severe liver or renal disease.

Phlebography

Bilateral ascending phlebography was performed before treatment by the method described by Rabinov and Paulin (1972) and this was repeated on the fifth or sixth day after admission. All radiographs were assessed on a blind basis.

Assessment

On admission to the trial, a detailed proforma was completed for each patient. The patients' legs were examined daily both clinically and by Doppler ultrasound using the methods and criteria of Evans and Cockett (1969). The appearance of symptoms such as chills, rigors, nausea and vomiting was recorded and the frequency of minor and major bleeding episodes was noted.

Diagnosis of pulmonary embolism during therapy

After admission to the study patients underwent spirometry before and after bronchodilators, posteroanterior and lateral chest radiography and, in most cases, a four-view perfusion lung scan ($^{99}Tc^{m}$ MAA Nuclear Chicago Pho-Gamma III camera). Wherever possible, the chest radiograph and perfusion lung scan were repeated on the seventh post-admission day. These results were blindly assessed and a numerical score recorded which reflected the degree of confidence with which a perfusion defect was regarded as representing a pulmonary embolus (Immelman et al., 1979).

Laboratory tests

A full blood count and serum urea were obtained before therapy and the haemoglobin estimation was repeated after the fifth day of treatment. The platelet count, prothrombin index, serum fibrinogen, fibrin degradation products and thrombin clotting time estimations were performed before, during and after the infusion of streptokinase. Because this trial was studying a standard dosage schedule of streptokinase no adjustment was made according to the above results.

Administration of drugs

Streptokinase (*Kabikinase*): A loading dose of 600 000 units of streptokinase was given by infusion over a period of 30 min. Thereafter a constant infusion of streptokinase at a rate of 100 000 units hourly was given for 3 days by means of a

† Died.

constant infusion pump. On completion of the streptokinase, full dose heparin was commenced and maintained for 4 days, the dosage being adjusted to maintain the Lee–White clotting time to at least two and a half to three times normal.

Heparin: Upon diagnosis, 10 000 units of heparin were given immediately by intravenous injection. Thereafter 10 000 units were given intravenously 6-hourly using a constant infusion pump. The dose was adjusted to maintain the clotting time to at least two and a half to three times normal. Treatment was continued for 7 days.

Other drugs: Patients received 100 mg of hydrocortisone 15 min before the administration of the first dose of streptokinase. This was repeated 6-hourly for the duration of streptokinase infusion. Warfarin 20 mg was given as a loading dose to both groups of patients 36 h before heparin therapy was terminated and warfarin was continued for at least 8 weeks with the dose being adjusted to maintain the prothrombin index at 40–60 per cent.

Other measures

All patients were confined to bed during treatment. The foot of the bed was raised by 60 cm and elastic support to the legs was provided (TED Anti-embolism Stockings: Kendall Co.). An intravenous catheter was inserted into the median cubital vein before therapy was commenced and this was maintained for the entire 7 days of intravenous therapy. No intramuscular injections were given during treatment.

Follow-up

During follow-up the sequelae of deep vein thrombosis which were evaluated included aching, oedema, varicose veins, venous claudication and skin changes including ulceration.

Ascending phlebography was performed 3 months after admission to the trial and was repeated at 12 months unless the patient was entirely asymptomatic. Cine-phlebography was performed 3 months after streptokinase in 9 patients.

Results

A total of 51 patients was included in this study: 26 received streptokinase while 25 received heparin. The two groups were well matched for age, sex, duration of symptoms and distribution of thrombi (*Table I*).

Streptokinase group (Table II)

In 3 of the 26 patients treated with streptokinase therapy was terminated early because of complications (*Table III*). In 2 of these patients, both of whom had undergone major abdominal surgery (cholecystectomy and sigmoid colectomy) 7 days previously, life-threatening bleeding occurred. In the remaining patient streptokinase was terminated because of a hyperpyrexial response. This latter patient developed a pyrexia of 40 °C during the first 15 min of therapy and the infusion was stopped and an anti-histamine administered. This event occurred early in the trial; however, it is possible that had it occurred later, when more experience had been gained, treatment would not have been stopped. None of these 3 patients showed lysis on the 5-day phlebogram. A further patient completed the full course of streptokinase but developed a large wound haematoma within the first 12 h of subsequent heparin therapy and 2 patients developed a pyrexia exceeding 39 °C while on therapy (*Table III*).

Table III: COMPLICATIONS OF TREATMENT IN THE TWO GROUPS

* Post-mortem examination
PE, Pulmonary embolus.

Of the 23 patients completing therapy, complete lysis of all visible thrombus was achieved in 9 patients, 90 per cent lysis in 5 and 80 per cent lysis in 3. Thus 17 (74 per cent) of the patients achieved clot lysis of between 80 and 100 per cent. One patient with phlegmasia caerulea dolens and peripheral venous gangrene showed a remarkably rapid clinical improvement, although there was only 30 per cent lysis of the deep system (Elliot et al., 1979). In the remaining 5 patients there was no significant lysis.

One patient, a 23-year-old woman, developed asymptomatic pulmonary emboli during treatment. She had initially presented with a 7-day history of pain in the left leg and was found to have an occlusive thrombus of the left iliofemoral segment (*Fig.* 1). No respiratory symptoms were present, chest X-ray and spirometry were normal, but a pre-treatment perfusion lung scan showed a small defect at the right base (*Fig.* 2). Phlebography on day 6 revealed total lysis of the thrombus (*Fig.* 3) and, although the patient remained otherwise asymptomatic with a clear chest X-ray, the repeat perfusion scan now showed multiple defects (*Fig.* 2). A xenon scan at this time showed normal ventilation of the poorly perfused areas.

Clinical examination at 3 months indicated that 16 out of the 17 patients with 80–100 per cent lysis had asymptomatic legs and on further follow-up to a mean period of 19 months, 12 patients remained asymptomatic while 3 had died of unrelated causes (*Table IV*) and 1 was lost to follow-up (*Table II*).

In contrast, the 9 patients who did not achieve substantial lysis after streptokinase fared less well. After a mean period of 19 months, 5 patients had symptoms of aching and oedema, 2 patients had venous claudication, 1 had died of carcinomatosis (*Table IV*) and one was lost to follow-up (*Table II*).

Phlebography was performed 3 months after therapy in 20 patients. In 2 patients partial rethrombosis had occurred whilst in 3 patients (who previously achieved 80–100 per cent lysis on day 5) the deep veins were shown to be completely clear. Cine-phlebography was performed 3 months after therapy in the 9 patients who had achieved 100 per cent lysis as shown on the 5-day post-treatment phlebogram. Normal valvular function was confirmed in 8 patients. All other patients with either a perfect or near-perfect result on day 5 maintained their good result. In the 9 patients who did not achieve initial substantial lysis (including 3 patients in whom streptokinase therapy was stopped because of complications) phlebography at 3 and in some cases 12 months showed considerable recanalization and collateral development but without restoration of valvular function.

Heparin group

No significant lysis was achieved in any of the 25 patients randomized to heparin therapy as assessed

KABIKINASE®

(pure streptokinase)

the right answer to existing thrombi

Kabikinase is now used internationally as a more effective method of treating deep vein thrombi, pulmonary emboli and arterial occlusions. Surgical clearance is frequently both hazardous and inconvenient and reported morbidity rates are as high as 60%. Heparin and other anti-coagulants can prevent further clot formation but have no effect on existing thrombi. Kabikinase rapidly potentiates the body's own ability to dissolve blood clots.

KabiVitrum

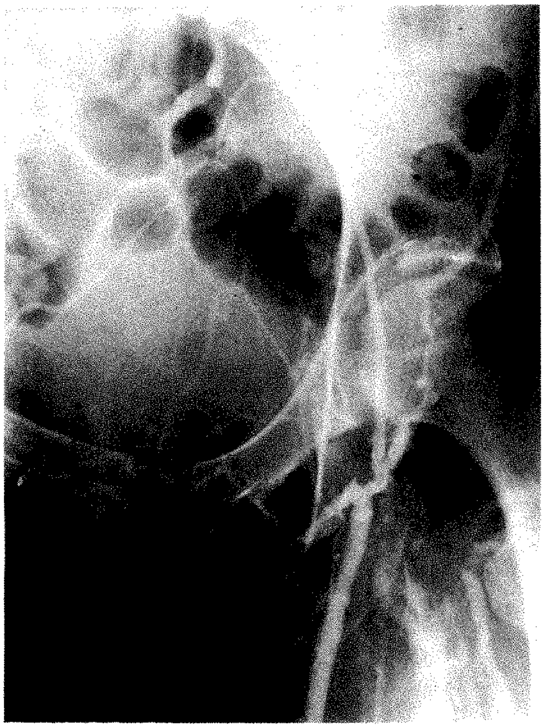

Fig. 1. Pre-treatment phlebogram of left lower limb showing an occlusive thrombus of the iliofemoral venous segment.

by phlebography on day 5. In fact, 2 patients showed further extension of thrombosis. There were no major bleeding problems.

Four patients in this group have died (*Table IV*). Two patients died from massive pulmonary embolism confirmed by autopsy. The first patient died on the sixth day of heparin treatment despite a whole blood clotting time of 16 min. The second patient was admitted with non-occlusive popliteal vein thrombosis: phlebography on day 5 revealed that there had been extension of the thrombosis into the superficial femoral vein (*Fig.* 4). This patient died on the sixth day of warfarin therapy when the prothrombin index was 27 per cent. In both patients autopsy revealed extensive, bilateral occluding thrombus involving either the main pulmonary artery or multiple major tributaries with a variable number of pulmonary infarcts. No other primary cause of death was revealed.

Follow-up of the remaining 21 patients ranged from 6 to 33 months (mean 19 months). Only 2 patients had asymptomatic legs while 1 patient had had bilateral distal amputations following an aortic saddle embolus. All other patients had symptoms of aching and oedema, 4 had venous claudication and 1 patient had developed a venous ulcer. Most patients showed considerable recanalization and collateral development on the third or twelfth month phlebogram but without restoration of any valvular function.

Discussion

It is impossible to determine accurately the magnitude of the disability resulting from the postphlebitic syndrome. As early as 1928 Merz estimated that to the community as a whole the cost of the management of chronic venous ulcers of the leg was equal to the cost of pulmonary tuberculosis. Recently O'Donnell et al. (1977) reviewed 21 patients with acute iliofemoral venous thrombosis and showed that the average patient spent almost US $40 000 on medical expenses during a 10-year period.

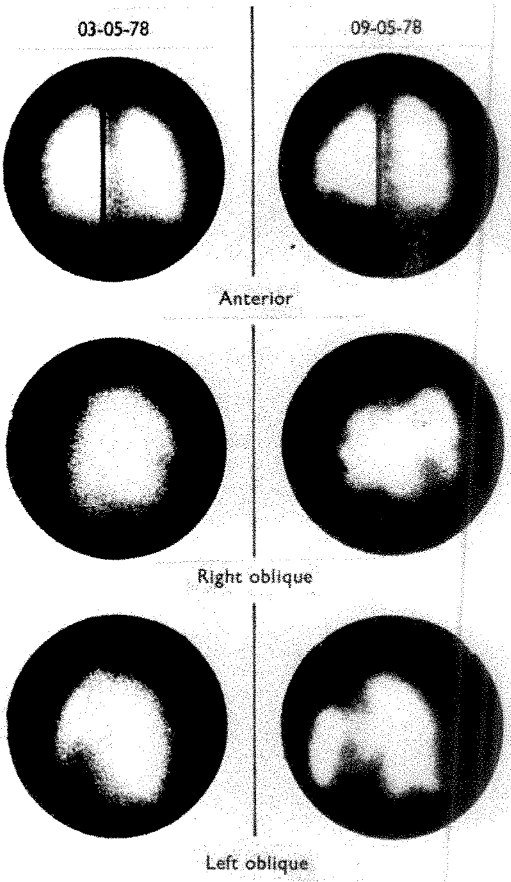

Fig. 2. Pre- and post-treatment pulmonary perfusion scans of a 23-year-old female with iliofemoral venous thrombosis treated with streptokinase. Post-treatment perfusion scan revealed multiple defects with a normal chest X-ray and ventilation scan indicating that an asymptomatic pulmonary embolism had occurred during treatment.

At the present time there is no evidence that thrombolytic therapy will decrease the incidence of pulmonary embolization from an established deep vein thrombosis. Thus the rationale for this form of therapy, which is both expensive and potentially dangerous, is the dissolution of thrombus with the preservation of venous valves and thus the prevention of the postphlebitic syndrome. If this could be proved, the cost of thrombolytic treatment would be fully justified. Significant lysis at the termination of therapy is on its own meaningless unless it can be shown that this clearance can be maintained on long term follow-up.

Previous randomized studies comparing streptokinase with heparin (Kakkar et al., 1969; Tsapogas et al., 1973; Porter et al., 1975; Arnesen et al., 1978) showed that complete lysis with restoration of venous valvular function was found in approximately 30 per

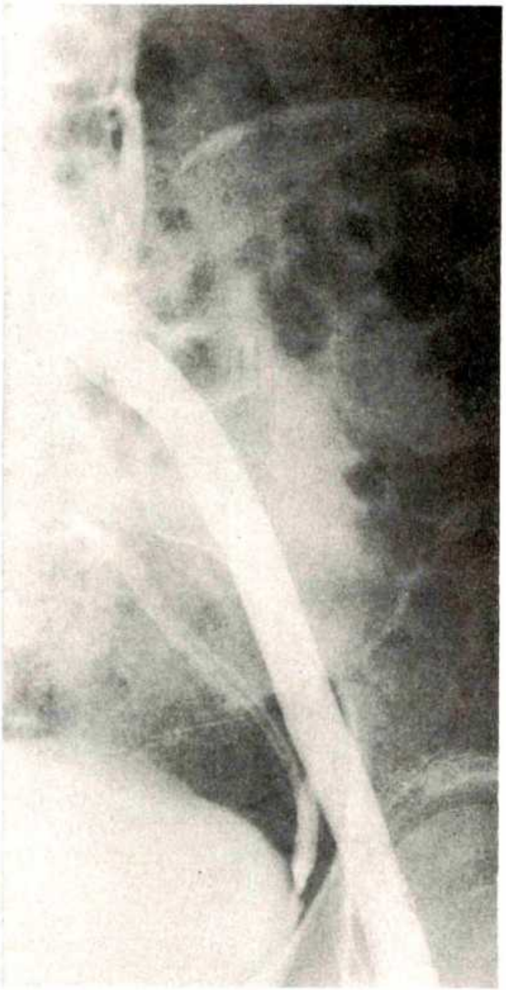

Fig. 3. Phlebogram after streptokinase therapy (day 6) showing complete lysis of the iliofemoral venous segment.

Table V: THERAPEUTIC RESULTS OF STREPTOKINASE AND HEPARIN IN DEEP VENOUS THROMBOSIS

	Heparin	Streptokinase
No. of patients	25	26
Complete (or substantial) lysis (>80%)	0 (0%)	17 (65%)

Table VI: FOLLOW-UP OF HEPARIN/STREPTOKINASE PATIENTS (MEAN 19 MONTHS)

	Heparin	Streptokinase
No. of cases	25	26
Dead/massive pulmonary embolus	2	0
Dead/other causes	2	4
Asymptomatic pulmonary embolus during treatment	0	1
Lost to follow-up	0	2
Asymptomatic patients	2	12
Symptomatic patients	19	8
Venous claudication	4	2
Venous ulceration	1	0

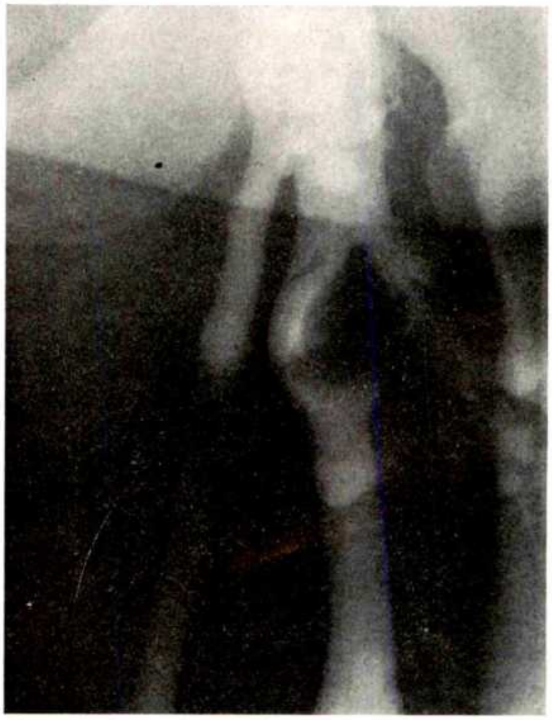

Fig. 4. Phlebogram (day 5) of patient being treated with heparin alone. Extension of thrombosis had occurred with fresh non-occlusive thrombus lying in the superficial femoral vein. Eight days later the patient died of a massive pulmonary embolism confirmed by autopsy.

cent of streptokinase patients, with substantial lysis in a further 65 per cent. In contrast, patients receiving heparin in these studies showed clot lysis of less than 10 per cent on post-treatment phlebography. These results are similar to those of our own study in which we found complete or substantial lysis (80–100 per cent) in two-thirds of our patients receiving streptokinase and in none of the patients receiving heparin (*Table V*).

A review of our streptokinase patients (*Table II*) suggests that the ideal patient for thrombolytic therapy is one with a non-occlusive thrombus and a clinical history of 7 days or less.

In 1968 Browse et al. suggested that occlusive thrombi were not amenable to thrombolytic therapy. However, in 1978 Arnesen et al. stated that they could find no difference in the degree of lysis achieved when treating either occlusive or non-occlusive thrombi. In the present series 8 patients had largely non-occlusive thrombus and all achieved degrees of lysis exceeding 80 per cent as shown on the 5-day phlebogram. In 2 of these patients with a late clinical presentation partial rethrombosis followed initially successful lysis.

In the 18 patients with largely occlusive thrombus 15 completed a full course of streptokinase and 9 of these patients achieved degrees of lysis exceeding 80 per cent on 5-day phlebogram and 8 remained asymptomatic on follow-up. Thus, although the results are a little less impressive for the patient with largely occlusive thrombus, our results indicate that streptokinase therapy should be considered for these patients if the clinical history is less than 7 days.

Follow-up of the two groups in this study reveals a higher incidence of postphlebitic complications in the heparin group commensurate with the absence of lysis in this group (*Table VI*). None of the heparin patients had a normal venous system at 3 months whereas 10 out of 26 streptokinase patients had a completely normal deep venous system.

In the streptokinase group 1 patient developed an asymptomatic pulmonary embolus during treatment. In the heparin group 2 patients died of massive pulmonary emboli while on adequate anticoagulation (*Table IV*).

The frequency and severity of major complications were greater in the group of patients treated with streptokinase (*Table III*). Two of the 3 patients who suffered major haemorrhage had undergone major abdominal surgery 7 days previously while the third had had an operation 20 days earlier. Bleeding complications can on the whole be prevented by careful patient selection, avoidance of thrombolytic therapy in patients within 10 days of major surgery, inserting an adequate intravenous catheter before commencement of therapy and avoiding all invasive procedures during therapy. Minor complications such as a slight pyrexia or bleeding around venepuncture sites were more common in the streptokinase patients than among the heparin-treated patients.

In 2 of the 3 streptokinase patients who suffered major bleeding complications bleeding occurred either during the last few hours of streptokinase therapy or during the first 12 h of subsequent heparin therapy. It is interesting to speculate on the mechanism involved. It is possible that as soon as the streptokinase infusion is stopped, less activator is formed and therefore the level of proactivator plasminogen begins to rise. However, as activator and proactivator plasminogen combine in a ratio of 1 : 9 molecules, it is possible that in this period excessive hyperplasminaemia is occurring with the associated risk of bleeding. Obviously the immediate infusion of heparin, as performed in this study, compounded this problem. We have therefore altered our drug schedule and now wait for approximately 4 h after cessation of the streptokinase infusion, until the thrombin clotting time has decreased to approximately twice the control value, before commencing heparin therapy.

All patients in this study who were treated with streptokinase received a standardized dosage schedule. We agree entirely with the findings of Marder et al. (1977) in that there appeared to be no correlation between the response to streptokinase (assessed by phlebography) and the serum fibrinogen, thrombin clotting time and fibrin degradation levels. The need for strict laboratory control can therefore be questioned because it is time-consuming and involves multiple venepunctures. We would stress, however, that constant clinical control is indispensable and that laboratory tests are required before treatment to detect any serious haemostatic defect and also after treatment to re-establish a base line for heparin therapy.

In conclusion, we feel that streptokinase therapy is the treatment of choice for phlebographically proved extensive thrombi of the deep veins, provided that the clinical history is no longer than 7 days, optimal results being achieved in patients with largely non-occlusive thrombus. Complications can largely be prevented by careful patient selection, close clinical observation and avoidance of all invasive procedures during therapy. Any surgical procedure within 10 days is a direct contraindication to streptokinase therapy.

Acknowledgements

We are extremely grateful to the staff surgeons, physicians and patients who cooperated so wholeheartedly in this study. Expert technical assistance was provided by Mrs G. Shaw, Mrs G. M. Wheeler and Mrs T. Wolfe. Financial assistance obtained from the South African Medical Research Council, the University of Cape Town Staff Research Fund, the Nellie Atkinson Trust and Pharmacal Ethicals is gratefully acknowledged.

Anticoagulant activity and operative blood loss after intrapulmonary heparin

CHARLES J. WRIGHT, JAYSEN MAHADOO AND LOUIS B. JAQUES*

SUMMARY

The safety and efficacy of heparin given by the intrapulmonary route are further assessed in this study. A single dose of heparin (2000 units/kg) was given by intratracheal instillation in dogs and measurements of plasma heparin concentration, whole blood clotting time and partial thromboplastin time made at intervals for 48 h. These values rose progressively and in parallel for 7 h and remained elevated for 48 h.

A series of operations was performed on dogs within 3 h of a single dose of intrapulmonary heparin (1500 units/kg). Operations involving minimal dissection (small bowel resection) and extensive dissection (resection of muscle) were performed in two separate groups. Within each group the animals were randomly given heparin or saline. In the limited dissection group there were no differences in operative blood loss, wound healing, or sequential haemoglobin and haematocrit measurements. In the group subjected to muscle resection there was increased postoperative wound drainage and a slightly greater fall in haemoglobin and haematocrit in those given heparin.

It is concluded that heparin is absorbed from the lung causing significant changes in coagulation parameters. Even with the relatively high dose of 1500 units/kg, operations were performed with minimal hazard. Intrapulmonary heparin may have important clinical applications after further investigation.

STUDIES by Windsor and Freeman (1964), Rosner (1965), Bardana et al. (1969) and Youngchaiyud et al. (1969) demonstrated that heparin given by the intrapulmonary route, in doses similar to those usually given intravenously, caused no significant change in coagulation parameters. The impression—subsequently proved to be erroneous—was thus gained that heparin is not absorbed by the lung. Recent studies by Jaques et al. (1976), Kavanagh and Jaques (1976), Mahadoo (1978) and Wright and Jaques (1979) have shown that a single large dose of intrapulmonary heparin (1500 units/kg) causes a moderate but prolonged hypocoagulable state, lasting from 2 days in dogs to 10 days in humans. Mahadoo (1978) has shown that the heparin is rapidly absorbed from the lung and that it probably exerts its prolonged effect by slow release from a cellular pool throughout the body.

The use of low dose heparin is now firmly established in the prophylaxis of thromboembolic disease and the preliminary studies suggest that the intrapulmonary route may be effective and convenient. This study was designed to measure the effect of intrapulmonary heparin on coagulation parameters and plasma heparin levels, and to assess the safety of intrapulmonary heparin when administration of the drug is followed by an operation.

Materials and methods

Anticoagulant effects of intrapulmonary heparin

Five dogs with a mean body weight of 26·0±3·4 kg (±1 s.d.) were lightly anaesthetized with intravenous sodium pentobarbitone 15–20 mg/kg. An endotracheal tube was inserted and a soft catheter then passed through the tube into a major bronchus. Sodium heparin, 2000 units/kg, was injected through the catheter and flushed with 2 ml of saline. Commercial porcine mucosal heparin was used in a concentration of 10 000 units/ml. The volume administered was therefore around 5 ml and in no case was any of the heparin or saline returned through the endotracheal tube after removal of the catheter. The dog was then extubated and allowed to regain consciousness.

Plasma heparin concentration was measured by the thrombin clotting time assay described by Penner (1974). Whole blood clotting time was measured by a standard modification of the Lee and White (1913) technique. One millilitre of blood is placed in each of three glass tubes of internal diameter 8 mm in a water bath at 37 °C. The first tube is gently tilted at 30-s intervals until the blood fails to flow up the side. The second and third tubes are sequentially handled in the same manner, and the end-point taken to be clotting in the third tube. In 30 preliminary experiments in dogs, this technique gave a control whole blood clotting time of 5·1±0·4 min (mean±1 s.d.). The activated partial thromboplastin time was measured by the Lancer coagulizer, using a photo-optical clot detection system. These measurements were made after induction of anaesthesia, and 3, 5, 7, 24 and 48 h after the heparin was administered.

Perioperative blood loss after intrapulmonary heparin

Two operations on dogs were chosen to assess the effect of intrapulmonary heparin on blood loss. Small bowel resection was selected as an operation that would usually be expected to cause minimal blood loss and a partial resection of sacrospinalis muscle as one that would cause significant haemorrhage.

Group A consisted of 10 dogs of body weight 21·8±2·9 kg. Each was anaesthetized with 20–25 mg/kg of sodium pentobarbitone, intubated and ventilated with a Harvard pump. Venous samples were taken for haemoglobin and haematocrit measurements. Using a random numbers table, half of the group received 1500 units/kg of heparin by the intrapulmonary route as described above and the other half received an equivalent volume of saline only. The surgeon (C. J. W.) was not aware which animals had received heparin and which saline until the entire series was complete. Midline laparotomy was performed and a 20-cm segment of distal small bowel excised with end-to-end anastomosis using a standard two-layer technique. The incision was closed without drainage and the animal was allowed to recover with food and water ad libitum. All operative blood loss was carefully sponged and measured. The haemoglobin and haematocrit were measured daily for 5 days and then post mortem examination was performed after a lethal intravenous dose of sodium thiopentone.

In group B there were 20 dogs of body weight 23·8±3·6 kg. Ten received heparin 1500 units/kg and 10 saline as described above. The experimental procedure was as in group A, with the following modifications. Each dog was placed prone on the operating table and approximately 50 g of sacrospinalis muscle on the right side were excised through a 15-cm skin incision. Multiple bleeding points were ligated as they were encountered. A closed suction tube drain was left in the wound, brought out through a stab incision and the skin wound sutured. The mass of muscle excised was weighed and the suction drain blood loss measured daily for 5 days. Measurements of operative blood loss, and of haemoglobin and haematocrit, were made each day as in group A.

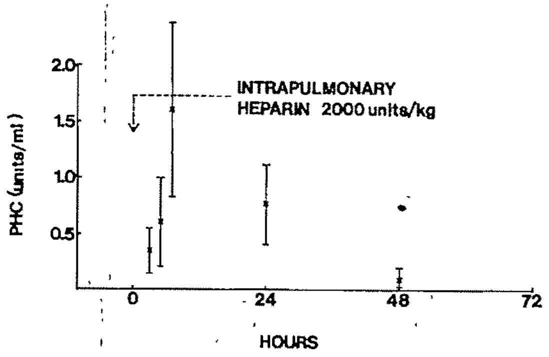

Fig. 1. Plasma heparin concentrations after intratracheal instillation of 2000 units/kg. Mean values±1 standard deviation.

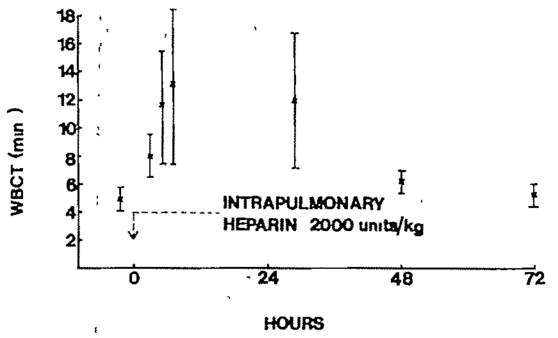

Fig. 2. Whole blood clotting time after intratracheal instillation of 2000 units/kg of heparin. Mean values±1 standard deviation.

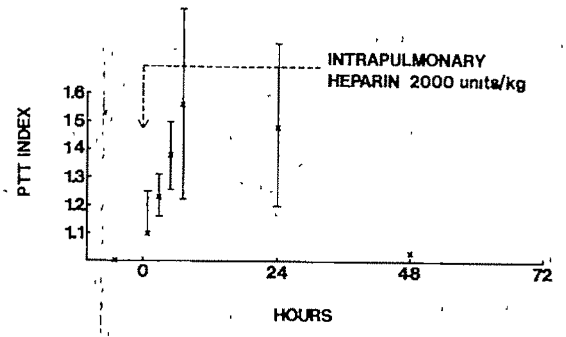

Fig. 3. The partial thromboplastin time is expressed as an index: each sample value divided by the control value. Mean values±1 standard deviation.

No blood was transfused in any of the experiments, but during the operative procedure an intravenous infusion of 500 ml saline was given.

Statistical methods

The means and standard deviations were calculated for each group of samples and group A was compared with group B by the Student *t* test for unpaired data. Measurements made at different times within each group were compared by the Student *t* test for paired data.

Results

Anticoagulant effects

The plasma heparin concentration was 0·34±0·2 units/ml 3 h after administration of intrapulmonary heparin and rose to a peak of 1·61±0·86 units/ml at 7 h. *Fig.* 1 shows that the variation of individual samples was wide, but that significant amounts of heparin were still present in the plasma 24 and 48 h after administration.

Table I: MEASUREMENTS RELATING TO PERIOPERATIVE BLOOD LOSS IN GROUP A

	Saline ($n=5$)		Heparin ($n=5$)
Operative blood loss (ml)	79±46	n.s.	66±44
Haemoglobin (g/dl)			
Control	13·3±1·5		13·7±1·5
24 h	13·7±1·4	n.s.	13·9±1·4
48 h	13·6±1·4	n.s.	13·6±1·3
Haematocrit (%)			
Control	41±5		43±5
24 h	43±5	n.s.	45±5
48 h	44±4	n.s.	43±6

Values given as mean±1 standard deviation.
Not significant: $P>0{\cdot}2$.

Table II: MEASUREMENTS RELATING TO PERIOPERATIVE BLOOD LOSS IN GROUP B

	Saline ($n=10$)		Heparin ($n=10$)
Weight of muscle excised (g)	50·6±12·3	n.s.	52·3±13·5
Operative blood loss (ml)	140±82	n.s.	116±70
Postoperative wound drainage (ml)	138±160	$P<0{\cdot}02$	465±411
Haemoglobin (g/dl)			
Control	14·0±1·0		13·2±1·4
24 h	13·9±2·1	n.s.	13·0±1·6
48 h	13·1±1·9	$0{\cdot}05<P<0{\cdot}1$	11·5±2·6
Haematocrit (%)			
Control	43±3		41±4
24 h	44±7	n.s.	41±5
48 h	41±6	$0{\cdot}1<P<0{\cdot}2$	37±8

Values given as mean±1 standard deviation.
Not significant: $P>0{\cdot}2$.

The whole blood clotting time (*Fig.* 2) rose progressively for 7 h and at 24 h was still more than twice the control level. The 48 h level (6·1±0·4 min) remained slightly but significantly higher than the control (4·9±0·4 min, $P<0{\cdot}025$).

The changes in the partial thromboplastin time were small (*Fig.* 3) but they followed a similar pattern to that seen for the plasma heparin concentration and the whole blood clotting time. The control value was defined as unity and subsequent measurements expressed as the ratio of sample to control.

Perioperative blood loss

Group A: Small bowel resection: No postoperative problems were encountered. The wounds healed by primary intention and the animals were fully active by the third postoperative day, with no observable difference between those given saline and those given heparin. The blood loss during operation and the sequential haemoglobin and haematocrit measurements are shown in *Table I.* Blood loss was minimal, the haemoglobin and haematocrit did not change and there were no differences between the heparin-treated and control groups for any of the parameters measured.

Group B: Muscle resection: The results are displayed in *Table II.* The amount of muscle resected and the blood loss during operation were similar in the heparin-treated and control animals, but the postoperative drainage was significantly higher after intrapulmonary heparin. The large standard deviations reflect the fact that individual measurements of total wound drainage over 5 days ranged from 20 ml to 563 ml and from 20 ml to 985 ml in animals given saline and heparin respectively. In the heparin-treated group the haemoglobin and haematocrit levels revealed a definite downward trend by 48 h, but because of wide individual variations the differences were not significant. Healing of the skin wound was uneventful in all animals.

Discussion

Rediscovery of the intrapulmonary route for heparin

The doses of heparin given to patients via the lung by Windsor and Freeman (1964), Rosner (1965), Bardana et al. (1969) and Youngchaiyud et al. (1969) were in the range of 10 000–40 000 units. The changes in the whole blood clotting time were so slight that the intrapulmonary route was rejected as a practical method of heparinization, as it was understood that a therapeutic effect required demonstrable anticoagulant activity. The realization that low doses of heparin, 5000 units subcutaneously every 8 or 12 h, are sufficient to inhibit activated factor $\bar{X}$ (Biggs et al., 1970) and the subsequent overwhelming evidence that low dose heparin markedly reduces the incidence of postoperative thromboembolic disease (Kakkar et al., 1971; Scottish Study, 1974; Kakkar, 1975; Venous Thrombosis Clinical Study Group, 1975) have led to widespread acceptance of the technique in surgical practice.

The efficacy of heparin in low doses also led to a re-evaluation in this laboratory of the intrapulmonary route of administration. Kavanagh and Jaques (1976) found that a single dose of heparin by intratracheal instillation in dogs (1000–2000 units/kg) caused the whole blood clotting time and the partial thromboplastin time to rise for 24–48 h, with a dose–response correlation. Jaques et al. (1976) reported the anticoagulant effects of intrapulmonary heparin in dogs, mice, rats and human volunteers. In all species, a single large dose caused a moderate but prolonged hypocoagulable state lasting from 2 days in dogs to 10 days in man. Intrapulmonary heparin causes no change in lung function or histology (Wright and Jaques, 1979) and no adverse effects were detectable either clinically or radiologically in the human volunteers.

The cellular pool hypothesis

Mahadoo (1978) found that in rats given tritiated heparin by intratracheal instillation, 40 per cent of the administered dose had left the lung 1½ h later and after 24 h only 10 per cent remained. The heparin was found to be taken up by the lung lymphatics, capillaries and alveolar macrophages. It has also been shown that there is a marked arteriovenous difference in plasma heparin concentration and that vascular endothelium takes up heparin against a huge concentration gradient (Hiebert and Jaques, 1976). This work has led to the hypothesis that heparin is distributed throughout the body from the lung and is then slowly released back into the circulation from this cellular pool to cause the prolonged moderate hypocoagulable state which is observed. This hypothesis is currently under critical investigation.

The safety of intrapulmonary heparin

This study demonstrates that a single large dose of heparin by intratracheal instillation in the dog (equivalent to 140 000 units in a 70-kg man) causes significant elevation of the whole blood clotting time and partial thromboplastin time for 48 h. *Figs.* 1–3 show that these changes run in parallel with the plasma heparin concentration. Such a high dose would not be required for a prophylactic regimen but a dose only slightly lower (1500 units/kg) was chosen for the experiments to assess blood loss during operations performed after intrapulmonary heparin. In the 'minimal dissection' operation, the heparin had no detectable effects (*Table I*), but in the 'major dissection' procedure postoperative drainage of blood from the wound was increased (*Table II*). This study did not permit the wide individual variations of postoperative blood loss to be correlated with plasma heparin concentrations as the two factors were measured in different experiments. There was no increased bleeding during the operations, which were all performed within 3 h of heparin administration. The increased postoperative wound haemorrhage may reflect the relatively high plasma heparin concentrations found 7–24 h later. It should be noted, however, that the muscle resection operation described here is the type of procedure in which many surgeons would consider low dose heparin therapy to be contraindicated (Blaisdell, 1978). The subcutaneous low dose heparin regimen is known to cause a small but significant increase in perioperative blood loss and it is interesting to note that the main problem is increased postoperative wound drainage (Allen et al., 1978).

Clinical relevance of intrapulmonary heparin

The experimental work suggests that intrapulmonary heparin may be useful in clinical practice. The subcutaneous low dose heparin regimen requires twice daily injections for 5–7 days with the attendant risks of dispensing errors. A single intrapulmonary dose may provide the moderate level of hypocoagulability for the length of time which is required for the prophylaxis of thromboembolic disease. The first clinical study to establish the dose–response relationship for intrapulmonary heparin in patients is now in progress. Further work must elucidate the role of the cellular reservoir in the prolonged effects of intrapulmonary heparin and any species differences in response. A long term toxicity study involving the administration of heparin into the lung twice weekly is also underway. Depending upon the results of these studies a multicentric clinical trial of intrapulmonary heparin in the prophylaxis of thromboembolic disease in surgical patients will be conducted.

Conclusions

This study confirms that heparin is absorbed when given via the lung in dogs, causing a significant hypocoagulable state with significant levels of heparin in the plasma for at least 48 h. Operations may be performed safely in the dog after 1500 units/kg of intrapulmonary heparin, but increased wound bleeding occurs if major tissue dissection is involved. The intrapulmonary route for heparin administration merits further investigation as a possible means of achieving low dose heparinization.

HUGH F. FITZPATRICK*

SUMMARY

Levels of circulating T lymphocytes sensitized to breast tumour associated antigens (BTA) were correlated with pathological tumour stage or benign histopathology in preoperative studies of 180 patients by the antigen-stimulated active rosette-forming T cell (AgARFC) assay. Incubation of lymphocytes with allogeneic BTA extracts produced increased AgARFC compared with incubation without BTA. Significant levels of BTA-sensitive T cells were found in 78 per cent of breast cancer patients compared with 23 per cent of patients with benign disease ($P<0.0005$, by χ^2). Over 93 per cent of stage I cancer patients responded to BTA, compared with 69 per cent of stage II patients ($P<0.025$) and 59 per cent of stages III–IV patients ($P<0.005$). Twenty-nine per cent of 42 patients with fibrocystic disease were positive to BTA in contrast to 8 per cent of 25 patients with fibroadenomas. This was a 3·6-fold higher incidence of BTA-sensitive T cells associated with fibrocystic disease than with fibroadenomas, which was in agreement with the increased breast cancer risk rate associated with fibrocystic disease. These findings suggest that the AgARFC assay may detect early malignant change in fibrocystic disease. The AgARFC assay was found to reliably detect early invasive carcinoma.

CELL mediated immunity to breast tumour associated antigens has been investigated as a modality for improved early detection of breast cancer (Farrow, 1970; Herberman, 1976; Order, 1977; Waters, 1978). *In vitro* assays of peripheral blood leucocytes from breast cancer patients have demonstrated proliferation, cell mediated cytotoxicity, migration inhibition and adherence inhibition responses to tumour cells and to soluble tumour associated antigens (Harris and Sinkovics, 1976; Zimmerman et al., 1977). Many of these studies, however, reported either low sensitivity in the detection of malignancies or low specificity in the differentiation of malignant from benign lesions. Recently, we demonstrated T cell mediated immunity to soluble extracts of breast adenocarcinoma by the antigen-stimulated active rosette-forming T cell (AgARFC) assay (Ramey et al., 1979a, b). Peripheral blood T cells from breast cancer patients formed significantly higher percentages of active rosettes with heterologous erythrocytes when incubated with soluble breast tumour associated antigens than when incubated in antigen-free media. We now report the incidence and relationship of peripheral blood T cell responses to breast tumour associated antigens detected by the AgARFC assay, with tumour stage and benign histopathology in patients with clinical breast disease.

Patients and methods

Patients, histopathology and staging

One hundred and eighty inpatients at St Luke's Hospital Center were assayed for circulating T lymphocyte reactivity to soluble breast adenocarcinoma-associated antigens by the AgARFC assay. Heparinized venous blood samples drawn before biopsy or operative manipulation of breast lesions were obtained from 164 women with clinical breast disease. Following surgery the patients were classified according to clinical findings in the medical records and pathological diagnoses were obtained from the routine surgical reports of the Department of Pathology. Patients with mammary carcinomas were classified according to the post-surgical treatment–pathological staging modification of the TNM staging system (American Joint Committee for Cancer Staging and End-Results Reporting, 1977). Patients with benign mastopathy were grouped according to the dominant lesion of the biopsy specimen: (*a*) fibrocystic disease, (*b*) fibroadenoma, (*c*) periductular or perivascular inflammation and (*d*) other benign lesions (including fibrosis, ductal ectasia, ductal or lobular hyperplasia and intraductal papilloma). Sixteen patients with non-mammary carcinomas of a variety of organs were also assayed preoperatively for lymphocyte activity to breast tumour associated antigens. Patients who had received radiation therapy or immunosuppressive drugs, or who had a past history of treated breast carcinoma were not included in this study.

Preparation of breast tumour associated and histocompatibility antigen extracts

Soluble breast tumour associated antigens (BTA) were prepared from fresh tumour tissue (histologically well-differentiated adenocarcinoma) obtained from two radical mastectomy specimens by extraction techniques which have been described previously (Ramey et al., 1979b). In brief, soluble antigen preparations of each tumour (designated BTA_1 and BTA_2) were made by hypertonic potassium chloride extraction of homogenates of minced tumour tissue (2 g wet tumour per 2 ml of 3 M KCl solution) at 4 °C for 16 h. Extracts were ultracentrifuged at 16 000 *g* for 60 min and the supernatants were dialysed three times against 200 volumes of 0·9 per cent NaCl. Dialysates were then centrifuged at 10 000 *g* and the supernatants of the tumour extracts were stored in aliquots at −20 °C. Aliquots were thawed once at room temperature and diluted 1 : 10 in fresh Hank's balanced salt solution (HBSS, Gibco, Long Island, New York) adjusted to pH 7·4, prior to use in the AgARFC assay.

Parallel extracts of peripheral blood lymphocyte histocompatibility antigens (HA) were prepared from heparinized venous blood drawn before mastectomy from the tumour donors (designated HA_1 and HA_2), corresponding to BTA_1 and BTA_2). Lymphocytes were isolated by Ficoll–Hypaque density flotation, washed in HBSS and extracted (10^9 lymphocytes per 20 ml of 3 M KCl) for 16 h at 4 °C (Reisfeld and Kahan, 1970). Ultracentrifugation, dialysis and storage of aliquots were performed as described above. Histocompatibility antigen extracts were diluted to a concentration of 5×10^6 cell-equivalents per ml of HBSS at pH 7·4 before use in the AgARFC assay.

AgARFC, ARFC and TRFC assays

The AgARFC assay for T cell sensitization to soluble antigens has been described in detail elsewhere (Hashim et al., 1977; Ramey et al., 1977; Hashim et al., 1978) and application of this assay to soluble human HA (Burrows et al., 1978) and to

INJECTABLE

ZINACEF

cefuroxime sodium

A BROADER SPECTRUM THAN MOST ANTIBIOTICS

In hospital practice Zinacef has been found to be particularly appropriate in the treatment of serious acute infections.
Zinacef has high resistance to beta-lactamase enzymes, high intrinsic bactericidal activity and, in a recent trial in eighty-six patients with purulent chest infections, was shown to be clinically superior to ampicillin.[1]
Zinacef has shown a low incidence of side effects, is well tolerated and has a wide margin of safety.

ZINACEF—A MAJOR ADVANCE IN FIRST-LINE ANTIBIOTIC THERAPY

1. Pines, A., Raafat, H. and Mullinger, B. M. (Details on file)

Prescribing information

Presentation
Vials of 250mg, [illegible] and infusion packs of [illegible] grams [illegible] containing [illegible] sodium.

Indications
Serious bacterial [illegible] where the causative organism has not yet been identified.

Conditions [illegible]
  Chest infections
  Septicaemia
  Soft tissue infections
  Obstetric and gynaecological [illegible]
  Bone and joint infections
  Ear, nose and throat infections
  Meningitis
  Gonorrhoea

Dosage
[illegible]
Severe infections [illegible] frequency of injections can be increased to six hourly if necessary giving [illegible] doses of [illegible] grams [illegible]

[illegible] in three or four divided doses. 60mg/kg/day [illegible] most infections.

[illegible] three divided doses.

[illegible] 750mg [illegible]

Contra-indications
Hypersensitivity to cephalosporin[illegible]

Precautions
Cephalosporins may in general be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria.
Cephalosporins interfere with tests for glycosuria which use copper reduction [illegible] ferricyanide method, and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.

Side effects
Adverse reactions are rare and generally mild and transient, e.g. rashes, gastro-intestinal disturbance, candida infection, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes, transient pain after [illegible] injection.

Storage
Protect from light.

Product Licence number [illegible]

Price to Hospital [illegible]

A GENTLER APPROACH TO THE TREATMENT OF BREAST CANCER

Too often, victims of breast cancer must also suffer the unpleasant side effects of combination cytotoxic chemotherapy.

'Nolvadex' offers a gentler alternative, particularly in post-menopausal women with predominantly soft-tissue disease or metastases. Up to 70% of such patients have responded to 'Nolvadex'[1] yet side effects of treatment are far fewer and much less distressing than with cytotoxic chemotherapy or with additive endocrine therapy.[2]

Moreover, a simple oral dosage means that patients may continue with 'Nolvadex' treatment in their own homes.

BTA (Ramey et al., 1979a, b) has been previously reported. In brief, peripheral lymphocytes, isolated from heparinized venous blood samples by Ficoll–Hypaque density flotation, were washed in HBSS, incubated with latex microparticles to label monocytes and suspended in 10 per cent minimal essential medium. Aliquots containing 300 000 lymphocytes per 0·05 ml were incubated in the presence of equal volumes of BTA for 15 min at 37 °C. Incubation was continued for 60 min following addition of 0·05 ml of sheep erythrocyte-adsorbed, gamma globulin-free fetal calf serum. Washed sheep red blood cells (SRBC) (0·05 ml of 0·25 per cent suspension) were added and the mixture was centrifuged at 200 *g* for 5 min. The pellet was gently resuspended and a minimum of 200 lymphocytes were counted on a haemocytometer at 400 times magnification to determine the percentage of rosette-forming lymphocytes (those having three or more adherent SRBC). Non-stimulated active rosette-forming T cells (ARFC) were determined by the same techniques, with 0·05 ml of HBSS substituted for soluble antigen preparation. Total T cell (TRFC) levels were determined with 300 000 lymphocytes in 0·05 ml of HBSS added to 0·05 ml of 2 per cent SRBC and 0·05 ml of adsorbed fetal calf serum, centrifuged at 200 *g* for 5 min and incubated for 60 min at 25 °C. All assays were performed in duplicate.

Nomenclature, calculations and statistical treatment

The subpopulation of peripheral blood lymphocytes that responded to *in vitro* incubation with specific soluble antigen was calculated as the difference between the percentage of antigen-stimulated active rosette-forming T cells (AgARFC, incubated in the presence of antigens) and the non-stimulated active rosette-forming T cells (ARFC, incubated in the absence of antigens). This difference was expressed as the percentage (AgARFC–ARFC). Patients in whom the percentage (AgARFC–ARFC) with either BTA_1 or BTA_2 exceeded 5·5 per cent (the 99·5 per cent upper confidence limit for replicate variation of percentage ARFC determinations for the entire group of patients) and in whom the percentage (AgARFC–ARFC) for corresponding HA was less than 5·5 per cent were designated as testing-positive for circulating BTA-sensitive T cells. All other patients, including those in whom the percentage (AgARFC–ARFC) was greater than 5·5 per cent with BTA *and* with HA, were considered to be negative for sensitization to BTA. All group results were expressed as the mean ± the standard error (s.e.) and group means were analysed by the two-tailed Student's *t* test. Significant differences between the incidences of positive patient responses in each patient group were determined by χ^2 analysis.

Results

Sixty-four of the 164 patients with breast lesions studied preoperatively were found to have breast carcinoma at operation: 31 with stage I, 16 with stage II and 17 with stages III or IV disease. The remaining 100 patients had benign histopathology on biopsy: (*a*) 42 had fibrocystic disease, (*b*) 25 had fibroadenomas, (*c*) 10 had periductal or perivascular inflammation and (*d*) 23 had other benign lesions (fibrosis, ductal ectasia, ductular or lobular hyperplasia, or intraductal papilloma).

Cellular sensitization to BTA in malignant and benign breast disease

Fifty of 64 breast cancer patients (78·1 per cent), all stages, were found by preoperative assay to have greater than 5·5 per cent (AgARFC–ARFC) differences upon incubation with BTA_1 or BTA_2. This incidence of circulating T cells sensitized to BTA in breast cancer patients was significantly higher than the 23·0 per cent of 100 benign mastopathy patients shown to have cellular sensitization to BTA ($P<0{\cdot}0005$, *Table I*). These values were also higher than the 12·5 per cent of non-mammary carcinoma patients responding to BTA ($P<0{\cdot}0005$, *Table II*) in the AgARFC assay.

Table I: CIRCULATING BTA-SENSITIVE T LYMPHOCYTES DETECTED BY THE AgARFC ASSAY IN MALIGNANT AND BENIGN BREAST DISEASE

* Percentage (AgARFC–ARFC) greater than 5·5 when incubated with BTA.

Stage–response relationship in breast carcinoma patients

An inverse relationship between the pathological stage of breast carcinoma patients and the incidence of BTA-sensitive T lymphocytes was observed (*Table III*). Twenty-nine of 31 patients (93·5 per cent) with early invasive carcinoma, without axillary nodal metastases (stage I), were found to have BTA-sensitive T lymphocytes. This incidence was significantly higher than the 68·8 per cent of patients with tumour in axillary nodes (stage II, $P<0{\cdot}025$) and the 58·8 per cent of patients with locally advanced or widely metastatic carcinoma (stages III–IV, $P<0{\cdot}005$) positive for BTA-sensitive T cells.

Sensitization to BTA in patients with benign mastopathy

Twenty-three of 100 patients found at operation to have benign breast pathology had greater than 5·5 per cent BTA-sensitive peripheral blood T lymphocytes. Classified according to benign histopathology, 12 of 42 patients with fibrocystic disease (28·6 per cent), 2 of 25 patients with fibroadenomas (8·0 per cent), 5 of 10 patients with predominant periductular or perivascular lymphocytic infiltrates (50·0 per cent), and 5 of 23 patients with other benign conditions (21·7 per cent) were demonstrated to have peripheral blood T cells reactive with either BTA_1 or BTA_2. There were significantly more patients in the fibrocystic disease group reactive to BTA than in the fibroadenoma group ($P<0{\cdot}05$, *Table IV*). Similarly, more of the group of patients with predominant perivascular or periductular infiltrates were shown to have circulating T cell sensitization to BTA extracts than the

TRFC/mm^3	1911±145	1448±206	1833±352
ARFC/mm^3	904±104	847±175	1147±218

* $P < 0{\cdot}05$ compared with %TRFC for stage II patients.

patients with fibroadenomas ($P < 0{\cdot}01$). However, all other differences among the groups of patients with benign mastopathy were not significant.

Differentiation between operable breast carcinoma and benign mastopathy

The rate of positive assay results was highest in patients with the best prognosis by stage (93·5 per cent in stage I). BTA-sensitive T cell detection by the AgARFC assay was positive in 85·1 per cent of patients with resectable breast carcinoma (stages I and II, combined). This overall incidence of positive BTA-sensitive T cell assays in patients with stages I and II breast carcinoma was significantly higher than in any of the benign mastopathy groups ($P < 0{\cdot}025$ to $P \ll 0{\cdot}0005$, *Table V*).

Peripheral lymphocyte counts and non-specific T cell subpopulations in patients with breast carcinoma

The mean values of peripheral blood lymphocyte counts, percentage or absolute number of circulating total T cells (TRFC) and percentage or absolute number of active T cells (ARFC), were not highly significantly different among stage I, stage II and stages III–IV breast carcinoma patients (*Table VI*).

Discussion

Positive responses to soluble breast tumour associated antigens by circulating T lymphocytes were detected in 93·5 per cent of patients with early invasive breast carcinoma by the antigen-stimulated active rosette-forming T cell (AgARFC) assay. Significantly lower percentages of patients with axillary nodal metastases, locally advanced disease and widespread breast cancer were positive. The relationship between pathological tumour stage and incidence of circulating BTA-sensitive T cells confirms previous findings reported from this laboratory (Ramey et al., 1979a, b). Furthermore, the relationship of decreasing cell mediated immune responses to BTA with advancing tumour stage shown in this study is in agreement with other reports which demonstrated depressed cell mediated immunity in advanced breast cancer. Disease stage and patient survival have been correlated with depressed delayed hypersensitivity reactions to autologous tumour transplants (Southam et al., 1962; Brunschwig et al., 1965) and to cryostat sections of autologous tumour tissue applied to skin windows (Black and Leis, 1971); however, the relationship of disease stage to skin test responses to soluble breast carcinoma tissue extracts has not been clearly defined (Hughes and Lytton, 1964; Stewart and Orizaga, 1971). Leucocyte migration inhibition (LMI) induced by BTA antigens has been shown to correlate with clinical stage and prognosis in several studies (Black et al., 1975; Roberts and Bathgate, 1975; Rieche et al., 1976). The highest degree of LMI reactivity to autologous and allogeneic breast tumour antigen was demonstrated in patients with *in situ* and early invasive breast carcinoma. Leucocyte adherence inhibition (LAI) induced by breast carcinoma antigen extracts was reported to be most frequent with leucocytes from patients with stage I or II breast carcinoma, while progressively lower rates of LAI reactivity were assayed with patients with stage III (45 per cent), or stage IV (29 per cent) disease (Grosser and Thompson, 1975; Fujisawa et al., 1977; Sanner et al., 1979). These results are in agreement with the incidence of BTA-sensitive T cells detected by the AgARFC assay in different pathological stages of breast cancer.

The mechanism underlying the unresponsiveness of T lymphocytes from patients with advanced breast cancer to BTA in the AgARFC assay has not been established. General parameters of cellular immune competence measured in this study were not significantly depressed in patients with stages II, III or IV breast cancer. In other studies, lymphoproliferative (LP) responses to alloantigens were depressed in patients with breast cancer, even when LP responses to mitogens were normal (Golub et al., 1974; Dean et al., 1977; Jerrells et al., 1978a, b). Mitogen-responsive T lymphocytes were correlated with the ARFC subpopulation whereas alloantigen-responsive T cells were correlated with the non-ARFC T cell subpopulation (Jerrells et al., 1978a). Similarly, BTA-sensitive T cells were detected in the non-ARFC subpopulation by the AgARFC assay, as were alloantigen-sensitized T cells in allotransplantation studies (Ramey et al., 1977; Burrows et al., 1978). Depressed LP reactivity of circulating alloantigen-sensitive T cells and depressed AgARFC reactivity of circulating BTA-sensitive T cells in patients with breast carcinoma may be the result of either depletion of such cells from the circulating lymphocyte pool, or excess of the sensitizing antigen which has been shown to block lymphocyte responses in the AgARFC assay (Hashim et al., 1979). Breast cancer serum has been shown to exert blocking activity on circulating leucocytes in a number of *in vitro* assay systems (Vanky et al., 1971; Whitehead et al., 1976; Jeejeebhoy, 1977; Steward, 1977), attributed to either antigen-antibody complexes (Sjogren et al., 1971; Matthews and Whitehead, 1976; Hoffken et al., 1977; Nordquist et al., 1977), or to excess circulating free tumour antigen (Grosser and Thomson, 1976; Fujisawa et al., 1977; Steward, 1977). Depression of BTA-sensitive T cells observed with AgARFC assays of peripheral blood lymphocytes of patients with advanced breast cancer could, therefore, represent an *in vivo* effect of either excess tumour antigen, or of tumour antigen-antibody complexes.

Recognition of breast tumour associated antigens by circulating T cells was observed in 23·0 per cent of patients with benign mastopathy. These responses may reflect the development of immunity to early malignant change in a continuum of breast disease progressing from benign mastopathy through 'pre-cancerous' hyperplastic lesions to *in situ* and eventually invasive carcinoma (Kern and Brooks, 1969; Black, 1976; Black et al., 1976; Cardiff et al., 1977). Recognition of BTA by patients with benign mastopathy has been reported in serologic assays (Humphrey et al., 1974), and LAI assays (Sanner et al., 1979) to a similar degree to that observed in the AgARFC assay. Higher rates of response in benign mastopathy have been reported with LMI (Cannon et al., 1978) and cell mediated cytotoxicity (Fossati et al., 1972; Avis et al., 1974; Oldham et al., 1975; Avis et al., 1976; Canevari et al., 1976) assays.

The incidence of BTA-sensitive T cells detected was significantly higher in patients with fibrocystic disease than in patients with fibroadenomas. This 3·6-fold increase in the incidence of positive assays for BTA-sensitive T cells in fibrocystic disease over the incidence with fibroadenomas parallels the increased risk of eventual breast cancer development associated with fibrocystic disease (Warren, 1940; Haagensen, 1956; Davis et al., 1964; Veronesi and Pizzocara, 1968). The question of whether these patients with fibrocystic disease will eventually develop invasive breast carcinoma was not addressed in this study; however, the data suggest that the AgARFC assay may be detecting early malignant change in fibrocystic disease. Such reactivity may have been responsible for the BTA-sensitive T cells noted in 5 of 10 patients with benign lesions consisting of perivascular or periductular lymphocyte infiltrates. Alternatively, these cases may represent reactivity to an agent similar to the murine mammary tumour viruses, which are known to cross-react with human benign and malignant proliferative breast lesions (Black et al., 1975; Muller et al., 1976).

The diagnostic accuracy of the AgARFC assay in the detection of resectable breast cancer by the criteria employed in this study was 95·3 per cent for stage I lesions and was 85·1 per cent for stages I and II combined. These percentages compare favourably with those reported for other *in vitro* assays, as well as with the detection rates which have been reported with mammography (Feig et al., 1977). Circulating T lymphocyte sensitization to breast tumour associated antigen was observed with significantly lower frequency in patients with advanced mammary carcinoma, non-mammary carcinoma or benign mastopathy. The incidence of BTA-sensitive T cells detected in patients with fibrocystic disease was higher than that in patients with fibroadenomas, by a factor which is in agreement with the increased breast cancer risk rate associated with fibrocystic disease. The data from this study suggest that the AgARFC assay reliably detected early invasive breast carcinoma, at the stage when it carries the most favourable prognosis. Longitudinal study of the patients assayed by the AgARFC method will assess the relevance of the detection of T cell sensitization to breast tumour associated antigens in determining prognosis of patients with breast carcinoma, and evaluate the possibility that detection of BTA-sensitive T cells in patients with fibrocystic disease reflects early malignant transformation.

Acknowledgements

We are grateful to the Clark Foundation for the support which made this study possible. We would also like to thank our colleagues who referred patients to this study: Drs Warren B. Burrows, Antoine Munther, Alexander J. Swistel and Duk Lee who contributed extensively to various phases of this research effort. Our thanks go also to Mrs Hermosa Paderon and Mr Cheng Yue Lin for their excellent technical assistance and to Mrs Peggy Mulrooney for her help in the preparation of this manuscript.

Seward's Stock Answer

Fine quality instruments-direct from stock

When you're in a hurry for surgical instruments, we're the best people to call.

Because it's always been Seward policy to keep ample stocks on hand, ready to meet orders in the quickest possible time.

Service like this has attracted more and more customers to Seward. Yet our range has lost none of its speed. Or quality.

So if you'd like to see things happen fast when you place your next instruments order, phone Seward.

Our stock answer will be just what you want to hear.

Debrisan beads
magnified x30 u
blue transmitted and
red incident light.

Creating the healing environment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing, such as bacteria and wound debris.

Pain, oedema and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast.

Use Debrisan on all moist suppurating wounds such as pressure sores and leg ulcers.

Patients can enjoy the benefits of the healing environment of the future. Today.

The distribution, size and density of the apocrine glands in hidradenitis suppuritiva

W. P. MORGAN AND L. E. HUGHES*

SUMMARY

The distribution, size and density of the apocrine glands in hidradenitis suppuritiva as compared with those in axillary hyperhidrosis and normal controls have been studied. There are no significant differences in the size or density of the apocrine glands in hidradenitis suppuritiva as compared with normal controls. The apocrine glands in axillary hyperhidrosis are significantly larger than those in axillary hidradenitis and in normal controls.

A simple method that can be used to demonstrate the distribution of the apocrine glands preoperatively is described. This has proved useful in delineating the area which it is necessary to excise to obtain complete apocrine gland excision in the diseased area. The apocrine gland-containing skin in the diseased region does not always correspond exactly to the hair-bearing area in that region.

HIDRADENITIS suppuritiva is a chronic, cicatrizing, suppurative disease of skin and subcutaneous tissue first described by Velpeau in 1839. The condition occurs in both males and females, though most series show a female predominance. It commences after puberty, most commonly in the second or third decade, and is usually considered to be a disorder of the apocrine glands as it is largely localized to areas where apocrine glands are found.

Treatment for this condition is unsatisfactory. Medical treatment is largely ineffective and seeks to palliate the established condition. Surgery cannot be considered entirely satisfactory since conservative resections are followed frequently by recurrence, and radical excisions are painful and result in a long period of morbidity before healing is complete. The unsatisfactory nature of current therapy may reflect the paucity of knowledge of these glands.

The apocrine sweat glands are simple, coiled, tubular glands with shunts and diverticula which lie mainly in the dermis, but large glands, as in the axilla, may extend into the subcutaneous fat, as much as 5 mm below the skin surface (Montagna and Parakkal, 1974). Apocrine sweating is adrenergically controlled but there is doubt as to the exact mechanism by which the catecholamines reach the glands. Hurley and Shelley (1960) suggest that apocrine sweating is divided into two phases. The first phase consists of secretion of sweat into the apocrine tubule and the second of expulsion of the apocrine sweat from the gland on to the skin surface. It is thought that the stimuli of apocrine sweating act by causing contraction of the myoepithelial cells surrounding the apocrine tubule, propelling sweat up the duct on to the skin surface. This rather meagre knowledge of the apocrine glands is largely confined to normal patients. There is little evidence to indicate whether apocrine glands differ quantitatively or qualitatively from normal in patients who develop hidradenitis.

Hidradenitis arises wherever apocrine sweat glands are situated. These are seen mainly in the axillae (where they are most dense), the external genitalia, the pubo-inguino-perineal and perianal regions. Certain modified apocrine glands also develop; the ceruminous glands of the external auditory meatus, the glands of Moll in the eyelids and the breast. The hair follicles in other regions usually fail to develop apocrine glands. However, the continued development of apocrine primordia in regions such as the scalp, the beard region and the trunk after the fifth month of intrauterine life results in heterotopic apocrine glands.

While the distribution of apocrine glands has been mapped in the general terms outlined here, no studies have been reported which define their distribution in exact terms, such as would be required to describe an operation for complete excision of the apocrine glands.

These deficiencies in the knowledge of the apocrine glands have led us to study two aspects of the background to hidradenitis suppuritiva. First, we have attempted to determine whether apocrine glands differ in number or size in patients with hidradenitis suppuritiva when compared with controls. Patients with hyperhidrosis (excessive eccrine sweat secretion) have also been studied in this regard. Secondly, an attempt has been made to develop a technique for demonstrating the distribution of apocrine glands prior to operation. This is being used both to delineate the area of skin which it is necessary to excise to obtain apocrine gland excision in patients with hidradenitis, and in the longer term, to determine whether the distribution of these glands differs from that in normal subjects.

Frequency and size of apocrine glands in hidradenitis

Methods

Pieces of skin 1 cm square were excised from the apices of the axillae in patients undergoing surgery for hidradenitis or hyperhidrosis, and in normal patients of similar age and sex undergoing other operations in this area. Similarly, specimens were excised from the hair-bearing skin overlying the pubic tubercle in patients with hidradenitis and normal patients undergoing operations in this region.

Following fixation of the specimen, 5-μm vertical sections of the skin were cut every 1 mm, resulting in 10 sections per specimen. After staining with haematoxylin and eosin, the number of glands in the ten sections was counted. Density was expressed as glands/cm^2. The index of size was determined by measuring the diameters of the apocrine glands in each skin specimen. The greatest diameter of an apocrine gland per 10 sections was taken as the index of the size in that skin specimen, since variation in the 10 sections through the spherical glands would result in less than maximal diameter in many cases.

In some of the axillary specimens there was near confluence of the apocrine tubules. Division of the tubules into separate units of apocrine glands was determined by the width of connective tissue partitions between the glands and by the height of the tubular epithelium. While the height of the tubular epithelium may be columnar, cuboidal or squamous, in general the height of the cells lining the tubules of one apocrine gland tends to be constant.

The third parameter measured was the total surface area of apocrine tubules in the 10 sections. A modified form of

planimetry utilizing the Quantimet 70 (Cambridge Instruments Ltd) was used for this purpose. The section to be studied was placed under the microscope of this instrument, which transmitted the image of the section on to a television screen. The margins of the apocrine tubules were then marked out on the screen by a light pencil, from which the Quantimet 70 calculated the surface area of the apocrine tubules, expressed in mm².

Results

Specimens were obtained from the apex of the axilla in 36 patients, 20 with hidradenitis, 6 with hyperhidrosis and 10 normal controls. The results obtained for the three parameters of size, density and total surface area are shown in *Table I*. As the results did not show a normal distribution, the significance was analysed using the Mann–Whitney U test.

There is no significant difference between the number of glands/cm² in any of these three groups.

The maximum diameters of the apocrine glands in hidradenitis did not differ from those in normal controls. However, the apocrine glands in hyperhidrosis were consistently large, the maximum diameters being significantly increased when compared with those of hidradenitis patients and normal controls.

There was no significant difference in the total surface area of apocrine tubules in any of the three groups. The median surface area of the apocrine tubules in hyperhidrosis was increased as compared to hidradenitis, but the result was only of borderline significance. The ratio of total surface area to number of glands/cm² is probably the best index of the average size of the apocrine glands in each group. This ratio was significantly increased in hyperhidrosis as compared with hidradenitis and normal axillary controls.

Specimens of hair-bearing skin over the pubic tubercle were studied in 24 patients, 15 hidradenitis patients and 9 normal controls. The results are shown in *Table II*. Two-thirds of the samples shown in each group contained no apocrine glands. This resulted in medians of 0 for glands/cm² and surface area in each group. In those specimens that did contain apocrine glands, there was no significant difference in the maximum diameter of each group.

Preoperative mapping of apocrine glands in hidradenitis

Methods

Wada's (1950) iodine/starch method is widely used in determining the area of maximal secretion of eccrine sweat in hyperhidrosis, but it does not differentiate between apocrine and eccrine sweat. Both forms of sweat will give a black spot when they facilitate mixing of the iodine/starch. To overcome this, we have developed a method in which eccrine sweating is blocked with atropine, following which oxytocin is given to stimulate apocrine sweating by contraction of the myoepithelial cells about the apocrine tubule. This is then demonstrated by the iodine/starch method.

It is necessary to ascertain prior to the procedure that the patient is normotensive and is not pregnant. The skin of the region under study should be shaved 48 h before the procedure because firm stroking of the skin expresses apocrine sweat and apocrine glands have a refractory period of 24–48 h after stimulation (Hurley and Shelley, 1960). Atropine (1·2 mg) is administered intravenously. The skin is then cleansed with alcohol, followed by the application of 2 per cent iodine in alcohol solution to the area under study and to the palm of the hand. When dry, a mixture of 75 g fine starch powder in 100 ml castor oil is applied to the area under study and to the palm of the hand. Oxytocin (2 i.u.) is given slowly intravenously. Within 3–5 min the black spots of apocrine sweating can be seen around the base of regional hair and at extrafollicular sites. The palm of the hand is used as a control to ensure that eccrine sweating has been completely blocked by the atropine, since this skin contains numerous eccrine but no apocrine glands.

The area of apocrine gland distribution in the axilla or pubo-inguino-perineal region was mapped out prior to radical excision for hidradenitis and the distribution of glands was determined in the resected specimen in the following way.

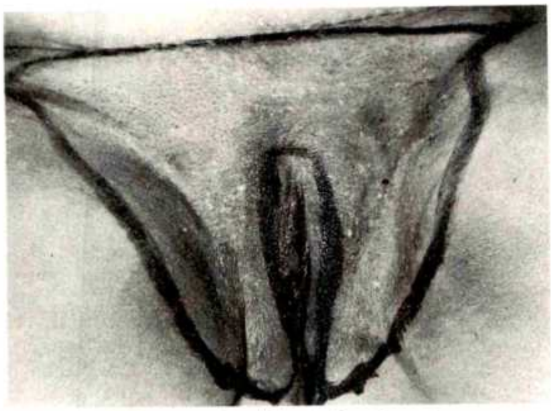

Fig. 1. Marked extent of excision in female perineum.

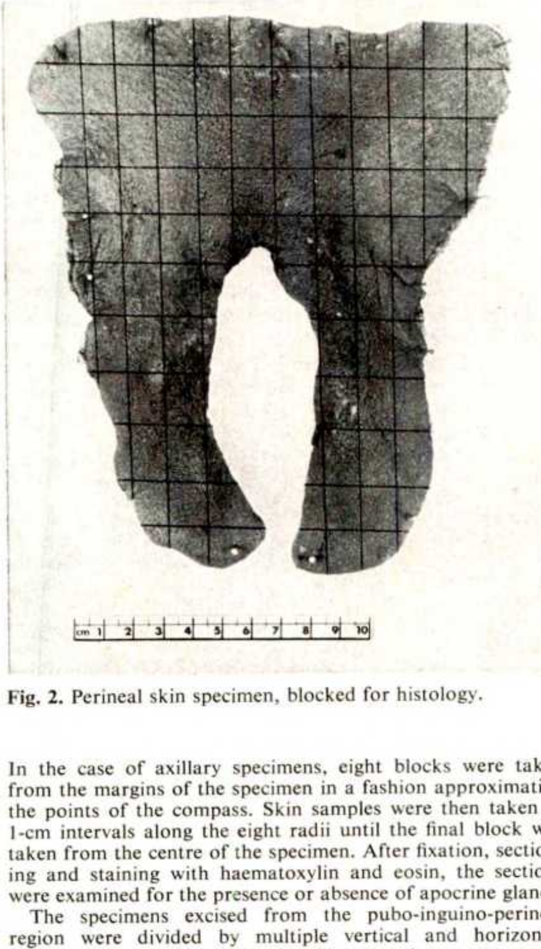

Fig. 2. Perineal skin specimen, blocked for histology.

In the case of axillary specimens, eight blocks were taken from the margins of the specimen in a fashion approximating the points of the compass. Skin samples were then taken at 1-cm intervals along the eight radii until the final block was taken from the centre of the specimen. After fixation, sectioning and staining with haematoxylin and eosin, the sections were examined for the presence or absence of apocrine glands.

The specimens excised from the pubo-inguino-perineal region were divided by multiple vertical and horizontal incisions into a grid of blocks. Three sections were cut at intervals from each block, and after staining the presence or absence of apocrine glands in the sections was noted (*Figs.* 1 and 2). In this way, a map of the apocrine glands in this region was drawn up.

Results

The atropine/iodine/starch and oxytocin method has been used to demonstrate the distribution of the apocrine glands in 11 axillary (6 male and 5 female) and 8 perineal (5 female and 3 male) regions. The sweat droplets appear as small black dots, mainly about the base of a hair, but also at extrafollicular sites. The spots are necessarily small, as the amount of sweat produced by one apocrine gland is 0·001 ml (Hurley and Shelley, 1960). In the axillae the apocrine glands are most dense in the skin of the hair-bearing area, but droplets in a less dense distribution may extend a further 2–3 cm outside this area (*Fig.* 3).

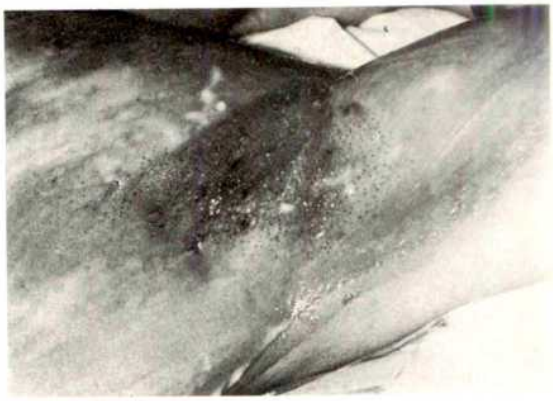

Fig. 3. Apocrine droplets in the axilla.

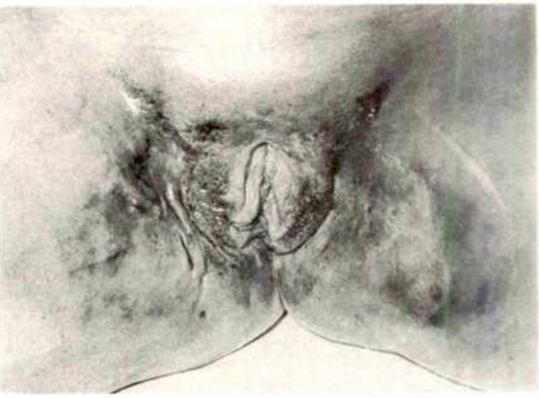

Fig. 4. The distribution of apocrine sweating in the female perineum.

In the perineum the majority of the apocrine glands, as demonstrated by the iodine/starch and oxytocin method, are situated in the skin of the medial halves of the flexural creases of the groins, extending posteriorly towards the anus. In the female they are present in the skin of the labia majora (*Fig.* 4) and in the male in the skin around the root of the penis and of the scrotum. Apocrine glands are also situated in the skin of the pubic region in a less dense fashion. The iodine/starch and oxytocin method also demonstrates the presence of variable thinly scattered heterotopic apocrine glands over the trunk.

Twenty-two axillary specimens (15 female and 7 male) and 9 perineal specimens (8 female and 1 male) were examined histologically. The maps of the apocrine glands so obtained confirmed the distribution of the apocrine glands in these regions, as demonstrated by the atropine/iodine/starch and oxytocin method. In the hair-bearing area of the axilla the glands can be near confluent, but in the surrounding

2–3 cm of skin apocrine glands can be found, often as solitary glands. In the perineum the glands were smaller and sparser than in the axilla.

Discussion

Shelley and Cahn (1955) produced keratinous plugging in the axillae of 12 normal male subjects by applying perforated belladonna adhesive tape to manually epilated axillary skin. At the end of 1 week all the subjects developed apocrine anhidrosis in these areas. Three of the 12 developed small, deep, tender nodules localized to the tape sites with the clinical appearance of hidradenitis suppuritiva. Histological study of the lesions showed keratinous plugging of the apocrine duct, dilatation of the apocrine duct and severe inflammatory changes limited to a single apocrine sweat gland.

Our work has not demonstrated any differences in the size or density of the apocrine glands in hidradenitis compared with those in controls. It is therefore possible that the primary pathology in hidradenitis suppuritiva is plugging of the apocrine ducts leading to an outlet obstruction of otherwise normal glands. Paradoxically, the size of the apocrine glands in axillary hyperhidrosis was significantly increased as compared with those in axillary hidradenitis and normal controls. A striking feature of the apocrine glands in hyperhidrosis was the uniformly large size of the glands in the samples examined. It is clear that the apocrine glands in hyperhidrosis are being subjected to some form of maximal stimulation, resulting in a full expression of their growth potential, but what form this stimulus takes is unknown. We are not aware of an association between hyperhidrosis and hidradenitis, and in fact the hyperactivity of the glands in hyperhidrosis might protect against hidradenitis, in that duct blockage seems to be the primary pathology.

The atropine/iodine/starch and oxytocin technique is a satisfactory method of demonstrating the distribution of the apocrine sweat glands. Its major practical use is to demonstrate the distribution of the apocrine sweat glands in a diseased region. Theoretically, it is then possible to achieve complete excision of all the apocrine gland-containing skin in that region and, hence, cure of the condition. Only a long term study can verify this. There are a number of possible limitations to the complete success of the method. While the major concentrations of the apocrine glands are well localized in both axillae and perineum, scattered apocrine glands are present over the trunk. It would not be possible in terms of morbidity and cosmesis to extend the excision to include these glands. In the male, the scrotal skin contains apocrine glands: while excision of diseased scrotal skin with a normal margin is acceptable to the patient, complete ablation of the scrotal skin is unlikely to be so. Recurrence of the condition could, then, occur either in the scattered trunk glands or in the scrotum. In the long term the technique can be used to compare the distribution of the apocrine glands in hidradenitis patients and normal controls.

Conclusions

Microscopic examination of skin samples obtained from the axillary and pubo-inguino-perineal regions did not show any significant difference in the size and density of the apocrine glands in cases of hidradenitis suppuritiva and normal controls. There was a significant increase in the size of the apocrine glands in axillary hyperhidrosis as compared with those in axillary hidradenitis suppuritiva and normal controls.

The iodine/starch and oxytocin method demonstrates the distribution of the apocrine glands in the axillary and pubo-inguino-perineal regions and this distribution has been confirmed histologically. It also demonstrates the presence of scattered apocrine glands over the trunk. The method demonstrates the difficulties of achieving complete apocrine gland excision in the diseased region. In both sexes there are scattered apocrine glands over the trunk, and in the male the skin of the scrotum contains numerous apocrine glands. Excision of these areas, if not diseased, would yield a high morbidity and probably be unacceptable to the patient. It would seem reasonable that the surgeon should excise the main concentrations of apocrine glands in the axilla or perineum, as demonstrated by the method, with all diseased skin, accepting that a small proportion of cases will recur because of scattered or scrotal apocrine glands.

Continent anal ileostomy with mucosal proctectomy: a bloodless technique using a surgical ultrasonic aspirator in dogs

W. J. B. HODGSON, J. L. FINKELSTEIN, PHILLIPA WOODRIFFE AND A. H. AUFSES JUN*

SUMMARY

At present, mucosal proctectomy with ileo-anal anastomosis is a difficult, time-consuming operation involving much blood loss, often associated with impaired postoperative continence. A new operation has been devised in our department in which a surgical ultrasonic aspirator, the CUSA™ System (Cavitron Corporation) was used to fragment directly and strip bloodlessly mucosa from the rectal wall in 20 dogs as part of a simple ileo-anal sleeve anastomosis. All dogs were closely followed for up to 10 months. The only operative mortality occurred in the first dog where the upper rectum sloughed because the superior haemorrhoidal artery was divided. Preoperative weight was regained within the first 2 months. Initially stools were loose and frequent. Within 2 weeks the daily stool count was 5–6 with gradual thickening to semisolid consistency by 6 weeks. Finally 3–4 normal stools were passed daily. Postoperatively, all dogs remained continent.

In pilot studies in animal and clinical work, (Hodgson et al., 1979; Hodgson et al., 1980a, b) a promising new surgical instrument has undergone preliminary evaluation, first at the Bronx Veterans Administration Medical Center and currently at the Mount Sinai Hospital, New York. This instrument incorporates, for the first time, ultrasonic energy in the actual performance of general surgical procedures. The initial evaluation demonstrated the capability of the ultrasonic aspirator to strip mucosa directly from the submucosa in the dog bowel. Furthermore, it could be done with minimal bleeding.

The first work in this field appeared in 1947, when Ravitch and Sabiston (1947) introduced the anal ileostomy with preservation of the anal sphincter in dogs. However, although it has since been used in patients, this procedure has not gained universal acceptance because it takes 2–3 hours of very careful dissection to perform the mucosal proctectomy (Martin et al., 1977). It was thought that the surgical ultrasonic aspirator might considerably reduce this time because of its ability to selectively fragment and aspirate tissue with a high water content and yet leave fibrous tissue relatively untouched. A study was therefore carried out in 20 dogs in which total colectomy was performed, leaving behind the rectum. Mucosal proctectomy was then carried out using the ultrasonic device which, on direct contact with the rectal mucosa, fragmented and aspirated it in its entirety. The endorectal pullthrough which followed was then done in the normal manner and the dogs observed for varying periods of time so that possible complications could be detected.

Materials and methods

The ultrasonic instrument

In 1969 the Kelman–Cavitron Phaco-Emulsifier™ was introduced for use in cataract surgery (Kelman, 1969). Subsequently results in over 500 cases have not demonstrated any particular problems which could be attributed solely to the Phaco-Emulsifier and the small percentage of cases which did develop problems was equivalent to the expected complication rate using other techniques (Kelman, 1973). Since then the Phaco-Emulsifier has become the preferred instrument in many centres (Jaffe, 1978). The Cavitron Ultrasonic Surgical Aspirator (CUSA™ System) is essentially a larger and more powerful version of the Phaco-Emulsifier and was first manufactured in February 1976. Initially it was intended to be used in neurosurgery and since Flamm et al. published their landmark paper in 1978, it is being used more and more frequently in this discipline.

The ultrasonic instrument basically consists of a control and power console operating with standard operating theatre electrical connections and to which is connected a gas-sterilizable handpiece. In general surgery a pencil grip surgical handpiece is used. It contains a vibrating suction device of hollow titanium oscillating longitudinally along its axis. This oscillation or vibration is produced by a magneto-strictive device which employs the principle of resonant vibration of a long slender metal structure. An alternating electric current, of exactly the frequency required to produce the mechanical vibration, is supplied by an electric oscillator in the console, and passes through the coil around the magneto-strictive transducers. When the alternating current is on, the transducer contracts and when the current is reversed, expansion of the transducer occurs beyond the original resting position. However, this contraction and expansion is not uniform but is very similar to the oscillations of a coiled spring attached to a weight. The tip contracts and expands simultaneously with the transducer. Because the hollow titanium tip is cone-shaped, this has the effect of amplifying the vibrations of the transducer and the resultant excursion of the tip, if plotted, would describe a sine wave. This is quite unlike low frequency reciprocating devices which vibrate uniformly and are limited, compared with the acoustic vibrators, in the velocities which may be obtained at their extremities.

The CUSA™ System operates at the ultrasonic frequency of 23 kHz. The vibration at the tip is imperceptible and has a maximum excursion of 150 μm and a total stroke of 300 μm. This vibration fragments tissue on contact and these tissue fragments are suspended in a stream of sterile normal saline flowing from the outside to the inside of the tip and removed from the operative field. This stream of normal saline is used at a rate of about 3–10 ml/min and can be varied as the operator desires. The ultrasonic vibration produces heat within the handpiece and at the tip. Reducing sterile irrigation increases the heat available at the tip so that a degree of cautery may be obtained. The magneto-strictive device is housed in a hollow stainless steel jacket and cooled by a stream of clean, but not sterilized, water drawn through the vacuum. If a defective seal or a crack in the housing occurred, the vacuum would prevent contamination of the handpiece. A plastic flue shrouds all but the last few millimetres of the tip and only this portion of the instrument is allowed contact with target tissue.

Maximal power available in the handpiece is approximately 75 W and depending on the requirements at the time of surgery

this level can be varied at the console. The console has an onboard computer logic system which directs and monitors the procedure and assures that the unit is properly primed and that vibration and irrigation is set and checked. On/off switches for the ultrasonic power and for irrigation are provided on a footpiece. The console will shut off ultrasonic power automatically if the control is disabled for any reason. Maximal aspiration is 24 mmHg and this can be reduced at the console. Aspiration automatically becomes inoperative when applying flush irrigation and is momentarily interrupted whenever tip vibration is interrupted. If the tip should become overloaded for any reason the console will automatically shut off power. Operation at present requires a surgeon and a technician. The technician sets up and primes the control and power console and is handed the end of the sterile tubing containing the handpiece. This tubing is plugged into the console and the surgeon then commences the procedure. At the end of the procedure the tubing is discarded and a new CUSA™ PAK is provided for the next operation as it is impossible to clean out tubing adequately between cases.

The experiment

Twenty dogs weighing between 15 and 25 kg were used. Haemoglobin, haematocrit values and white blood counts were obtained in all dogs before and after surgery. Antibiotics were routinely given preoperatively and postoperatively for 5 days.

Fluids ad libitum were provided but food was stopped 24 h preoperatively. Bisacodyl enemas were given the morning and evening before surgery and also on the morning of the operation. Anaesthesia was induced using intravenous Nembutal after which the dog was intubated. The skin was prepared and shaved and the abdomen opened in a standard manner. The vessels and mesentery of the colon were divided and the terminal ileum mobilized, dividing arcuate vessels and mesentery as necessary but taking care to keep the marginal vessels intact, until the ileum could be brought down to the perineum. Care was also taken, except in the first dog, to ensure that the superior haemorrhoidal artery was not divided. The colon was removed after placing stay sutures in the walls of the rectum. The ultrasonic instrument was used to divide the colon at the rectosigmoid junction.

Babcock clamps were applied to the stump of the rectum and, at about three-quarters of full power, the ultrasonic tip was applied to the mucosa of the rectum which was aspirated from the submucosa. Initially this could be done visually but after all the mucosa from the top 2 cm of rectal stump had been removed, the tip had to be operated blind. Subsequently, therefore, the tip was used to ream out mucosa from the rectal wall. Progress was determined from time to time by palpation and the operation was continued as far as possible from above. When it was clear that the distance was too great to continue to ream out mucosa, the ultrasonic instrument was moved to the anus and passed through the anus to complete the mucosal stripping. At this point the terminal ileum was tied off with a double umbilical tape in order not to soil the denuded rectum. After being pulled through the anus, it was partially opened and sutures placed between it and the skin of the anus. The redundant ileum was removed and four stitches were usually adequate to complete the anastomosis. After copious irrigation of the peritoneal cavity, the abdomen was closed in a standard manner and the dogs were maintained on intravenous fluids overnight.

After 24 h fluids were offered to the dog and usually within 48 h soft food could be provided. The dog would normally be eating a standard diet within 1 week.

Results

As experience was gained the time of the operation was reduced to below 2 h and in particular the mucosal proctectomy could be carried out in 15 min. Very little bleeding occurred and haemoglobin and haematocrit values remained the same postoperatively as they were preoperatively. No infections secondary to surgery occurred. All dogs were continent of faeces throughout the experiment. When the stool was liquid, it was evacuated in the normal manner. Some post-evacuation anal soiling occurred with these liquid stools. No nocturnal incontinence occurred.

A set pattern developed in that the stool consistency gradually improved from diarrhoeal to semisolid during the first month. The frequency of bowel movements increased from once to six times daily during this month, declined to four times daily at 4 months and to between two and three times daily thereafter. The semisolid stool became of normal consistency by 5 months although one dog was producing normal stool at 3 months.

Maximum weight loss occurred at 6 weeks and was more pronounced in the smaller dogs (*Fig.* 1). Overall, the weight loss was 2–3 kg but weight was regained in 4–5 months. The larger dogs regained weight sooner.

Maximum follow-up time was 10 months (*Fig.* 2). Dogs were sacrificed at intervals and abdomino-perineal resection performed to determine the state of the ileoproctostomy. The first dog died at 10 days postoperatively and was found to have sloughed its upper rectum. In this dog the superior haemorrhoidal artery had been taken because this vessel is removed during anterior resection in the human without problems. Clearly, in the dog, this prejudiced the outcome and thereafter the superior haemorrhoidal was carefully preserved. Initially, the anastomosis was done in two layers. First the ileum was sutured with 3/0 chromic catgut from serosa to the raw surface of the rectum. Then 3/0 catgut was used to suture the open end of the ileum to the anal skin. This double closure was abandoned when dog number 13 developed a fistula in the terminal ileum which led to faecal soiling for the first 2 weeks. The intraperitoneal portion of the rectum was not routinely sutured to the ileum. None the less, firm adherence occurred between the proximal rectum and ileum within 2 weeks. However, distally, the terminal ileum retracted up to a maximum of 2 cm from the anus. Sometimes this retraction occurred as early as 2 weeks postoperatively. None the less the result after mucosal regrowth was very satisfactory with the terminal ileum looking rather like the cervix uteri and the rectum like the vaginal vault (*Fig.* 3). Using 3/0 nylon to perform the distal anastomosis diminished retraction somewhat but the natural tendency for the terminal portion to narrow continued. This problem was finally solved by performing multiple punctures in the terminal ileum through the serosa and muscle, down to submucosa, with the ultrasonic aspirator. The anastomosis was then done with a single layer of four sutures of 3/0 vicryl and retraction and narrowing was virtually eliminated.

Discussion

In order to guarantee extirpation of unstable colonic mucosa, patients with precancerous colonic conditions such as familial polyposis or Gardner's syndrome have had to submit to total proctocolectomy and ileostomy and, furthermore, patients with ulcerative colitis who do not respond to medical treatment have also had to submit to such radical procedures. Unfortunately surgery is frequently deferred unnecessarily because of the unwillingness of the patient to take the step of total proctocolectomy and ileostomy. This unwillingness to accept surgery is based on the very real embarrassment which may occur to the ileostomate

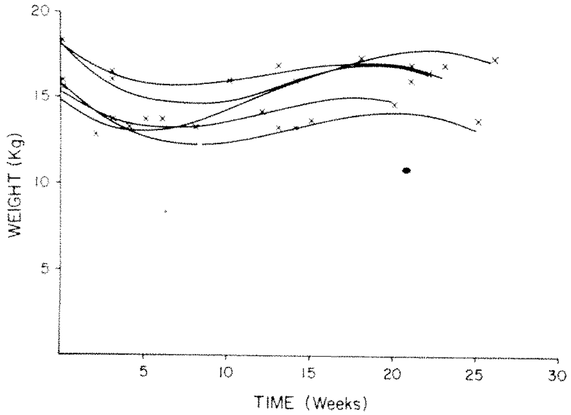

Fig. 1. Weight loss in dogs after colectomy and mucosal proctectomy with the ultrasonic aspirator.

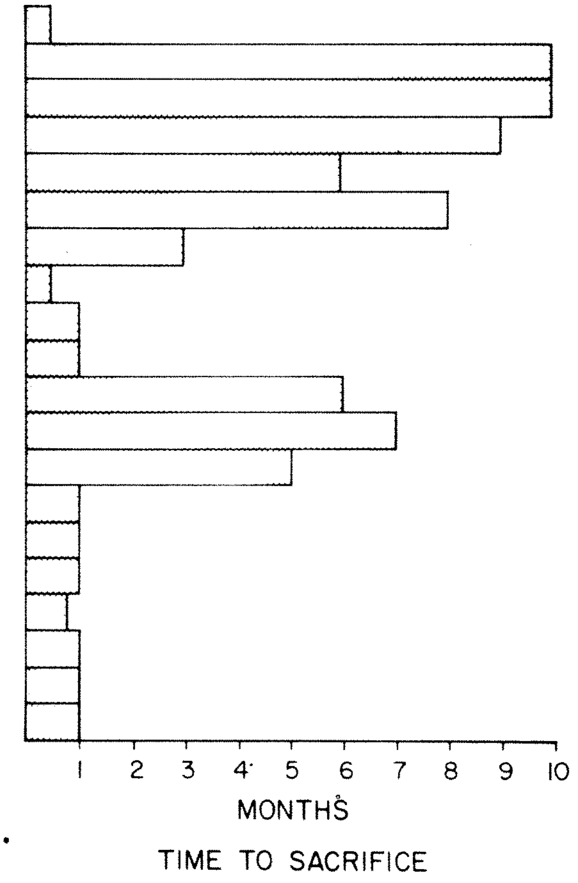

Fig. 2. Follow-up graph for dogs after colectomy and mucosal proctectomy with ultrasonic aspirator.

in courtship and marriage (Burnham et al., 1977), and to which must be added difficulties in sports and other strenuous activities. The presence of an ileostomy also precludes employment in the food industry. A Kock ileostomy has considerably assuaged these problems (Kock, 1969) but has not entirely eliminated them.

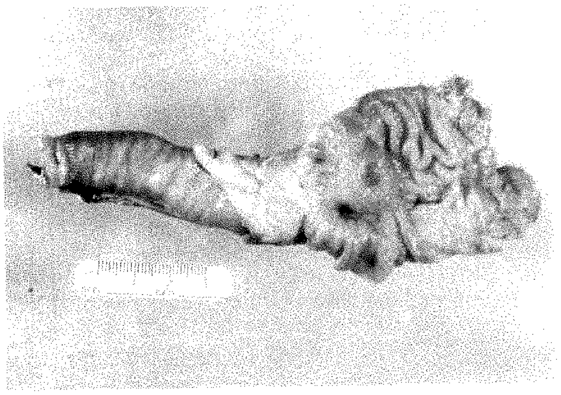

Fig. 3. Photograph of mucosal proctectomy and endorectal pullthrough 1 month after surgery.

The ideal operation for benign disease with potential malignancy would remove all potentially malignant mucosa and yet still preserve the anal sphincter. This not only avoids ileostomy, it also avoids the potential hazards of major pelvic dissections including possible damage to the nervi erigentes perhaps with poor bladder emptying and impotence in the male. A method of stripping the entire extraperitoneal rectal mucosa with minimum trauma, coupled with total abdominal colectomy and ileo-anal anastomosis, would best satisfy these criteria of an ideal operation. In addition, it would eliminate the lifelong attention necessary for the retained rectal segment and, of course, would obviate a permanent ileostomy for a benign disease. Ravitch and Sabiston (1947) and Ravitch and Handelsman (1951) successfully performed rectal mucosal proctectomy in dogs in 1947 and 1951; they described 7 patients with familial polyposis and ulcerative colitis who had undergone total colectomy and anal ileostomy. However, the operation, which was done from below and was quite traumatic, did not gain acceptance. In 1964 Soave modified the operation, performing it from above for the management of infants with Hirschsprung's disease. A similar technique was used by Jeffery, Hawley and Parks, who in 1976 reported a series of 5 patients who had a colo-anal sleeve anastomosis for diffuse cavernous haemangioma involving the rectum. However, the greatest experience of mucosal proctectomy and ileo-anal anastomosis was reported by Martin, LeCoultre and Shubert in 1977 who performed the procedure on 17 patients with ulcerative colitis. They found, even with the protection of the mucosal proctectomy with a temporary Turnbull loop ileostomy, that they had occasional postoperative problems due to haematoma formation and, in particular, once a temporary ileostomy was closed it took up to a year for complete control of the anal ileostomy to be obtained. Heiman et al. (1978) have been carrying out similar studies in patients with familial polyposis and in their admittedly small series of 4 cases have had no complications due to haematoma formation and have been able to manage the patients successfully after closure of the temporary ileostomy so that complete control of the anal ileostomy was obtained without medication within about 6 months.

These results would indicate that mucosal proctectomy and colo-anal or ileo-anal anastomosis should have a wider acceptance than is now the case. It is acknowledged that the difficult part of the operation is the mucosal proctectomy in which much bleeding occurs. A new modality, the surgical ultrasonic aspirator, has been demonstrated in animal work to be of use in mucosal stripping, which can be done quickly and with minimal blood loss. When applied to mucosal proctectomy, in dogs, this early promise was maintained and this part of the operation was considerably enhanced. Furthermore, the gratifying postoperative results of rapid control over the faecal stream, which is maintained, would seem to indicate that the procedure is in fact done with a minimum of trauma. Good healing was evident and no complications due to the procedure were encountered.

Acknowledgements

The authors wish to acknowledge a grant from the Cavitron Corporation and a grant from the Department of Surgery of Mount Sinai Hospital enabling them to carry out this work. We also wish to acknowledge the work of the staff of the Surgical Research Laboratories of both the Mount Sinai School of Medicine and the Bronx Veterans Administration Medical Center without whom this work would not have been possible; and to thank Lawrence Finkel for his invaluable assistance and Dr Joseph Williams for his histopathological reports.

Modulation of the immune response and control of tumour spread by a new synthetic compound

R. E. FALK, L. MAKOWKA, N. NOSSAL, J. A. FALK,
J. E. FIELDS AND S. S. ASCULAI*

SUMMARY

A small molecular weight biofunctional polymer, NED 137, has been investigated for its anti-neoplastic effect. Through its effect on the immune system, particularly the induction of B cell differentiation to antibody producing cells, this synthetic compound can retard tumour growth and prevent the development of distant metastases. Reactivity to tumour developed following administration of the NED 137. No toxicity has been observed. The polymer NED 137 is now being tested in phase I and phase II clinical trials.

THE use of adjuvant stimulation to improve an immune response to tumour antigen is a goal yet unattained. Recent evidence substantiates the view that human tumours carry tumour-specific antigens as well as tumour-associated antigens (Herlyn et al., 1979). This evidence implies that manipulation of the immune system could facilitate the development of a competent immune response to tumours. It is appropriate to assume that tumour-specific antigens are relatively non-immunogenic and that an immune response could inhibit metastatic disease while having a limited effect on primary tumour growth.

This report describes the investigation of an immune modulator known as NED 137. This polymer can selectively stimulate the B cell component of the immune system and our data indicate that it is able to stimulate antibody production to tumour. The present studies demonstrate the ability of the compound to decrease local tumour growth and to prevent the development of metastases. Anti-tumour reactivity developed following the administration of NED 137. This reactivity could be transferred to normal animals by serum. A comparison of NED 137 to standard non-specific adjuvants such as *Corynebacterium parvum* and BCG will be described.

Materials and methods

The animals utilized in these experiments were 2–4-month-old Fischer strain rats (F344), supplied by Microbiological Associates, Bethesda, Maryland. Animals were maintained in single cages and fed standard rat chow and water *ad libitum*.

The tumour used was a methylcholanthrene-induced carcinoma of the bladder (FBCa) in F344 rats. A 2×2 mm trochar implanted subcutaneously grows rapidly and a 2×2 cm mass is apparent at 7–10 days after implantation. Subcutaneous FBCa consistently metastasized to the lungs; pulmonary lesions were produced by intravenous injection of 10^6 FBCa cells. Subcutaneous FBCa can be surgically excised; however, the recurrence rate after excision at 10 days post implant is 100 per cent.

The development of an immune response to tumour was monitored *in vivo* using an adaptation of Bainbridge and Gowland's (1966) method of assessing allogeneic reactions. Animals were sensitized to tumour by excision of subcutaneous FBCa or by injection of 10^6 FBCa i.v.; test animals also received NED 137 intraperitoneally at 30 mg/kg. Sensitization to tumour-specific antigens was evaluated by the survival of ^{51}Cr-labelled FBCa in test animals, i.e. decreased survival of labelled cells indicated an increased recognition and destruction of FBCa. In this manner, an index of antigen recognition was computed with test values of retention divided by control values. Therefore, a lower index correlated with a greater degree of tumour destruction.

This assay was used in the examination of the mechanism of the anti-tumour reaction that developed after administration of NED 137 to tumour-bearing animals. The cytotoxic capacity afforded normal animals as a result of the transfer of either 1×10^8 spleen cells or 5 ml of serum from animals cured of tumour was measured.

The effect of NED 137 on tumour growth was compared with the effect produced by *C. parvum* and BCG. BCG (Connaught Laboratories, Toronto, Ontario) was administered i.p. at 0·1 mg per animal. Those animals receiving *C. parvum* (Wellcome Laboratories, Beckenham) were treated with 0·75 mg i.p. and i.v. weekly for 4 weeks. All three immunostimulants were administered to test animals after excision of their subcutaneous tumour.

Results

The survival of animals with *in situ* FBCa is shown in *Fig*. 1. Animals treated with NED 137 i.p. at 30 mg/kg showed prolonged survival as compared to control animals. Of even greater significance was that all the treated animals were found to be free of pulmonary metastases when autopsied, while all the control animals had extensive pulmonary metastases.

Fig. 2 illustrates the effect of NED 137 on tumour recurrence and the development of metastases after surgical excision of the primary tumour. Control animals showed 100 per cent tumour recurrence with subsequent death of all animals by 5 weeks post excision. When these animals were autopsied, all were found to have lung metastases. Animals treated with NED 137 i.p. at 30 mg/kg at the time of excision showed no local recurrences at 60 days post excision. When sacrificed at 60 days, all treated animals were free of pulmonary metastases.

In experiments where animals treated with NED 137 were not sacrificed, it was noted that recurrent tumour began to develop at 2 months post excision. Retention of ^{14}C-NED 137 indicated that levels of this compound in various body tissues decreased substantially at 60 days after i.p. administration. Therefore, the effect of multiple doses of NED 137 on tumour growth were examined in an effort to promote a more permanent anti-tumour response. As shown in *Fig*. 3, animals that had received four consecutive doses of NED 137 i.p. at 6-weekly intervals remained tumour-free. This group of animals has now been free of tumour for more than 6 months.

To assess the anti-tumour activity of NED 137 *in vivo* we monitored the survival of ^{51}Cr-labelled FBCa cells in control animals or animals treated with NED 137 (*see* Methods). As shown in *Table I*, treated

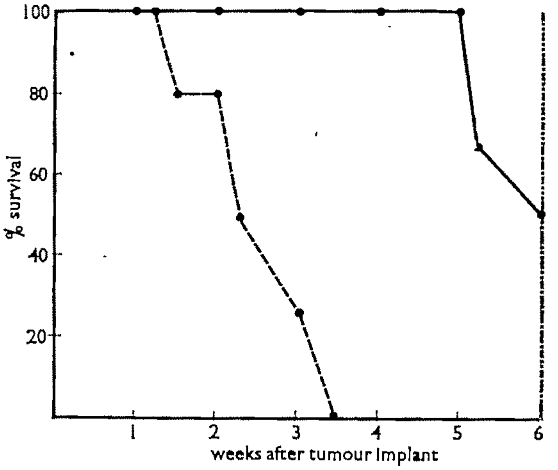

Fig. 1. The effect of NED 137 on survival with local tumour growth. Untreated control animals (● — — — ●) were dead from local tumour and metastases at a mean of 23 days after implantation. At 6 weeks after implantation, 50 per cent of the NED 137 treated animals (●——●) were still alive. These animals were sacrificed and found to be free of pulmonary metastases. ($n = 30$ for each group.)

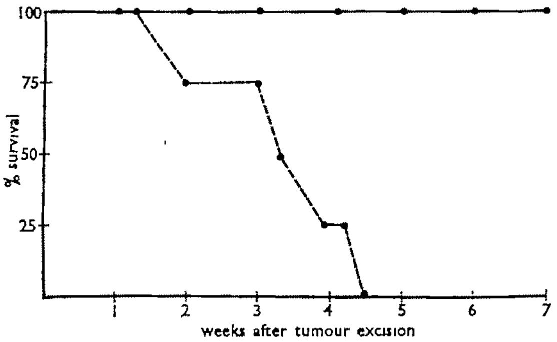

Fig. 2. The effect of NED 137 on survival after excision of local tumour. Subcutaneous tumour was excised and test animals received NED 137 at 10 days after tumour implantation. All tumours in untreated controls (● — — — ●) recurred and animals died at a mean of 35 days after excision. NED 137 treated animals (●——●) were still alive at 7 weeks after excision with no recurrence. ($n = 60$ for each group.)

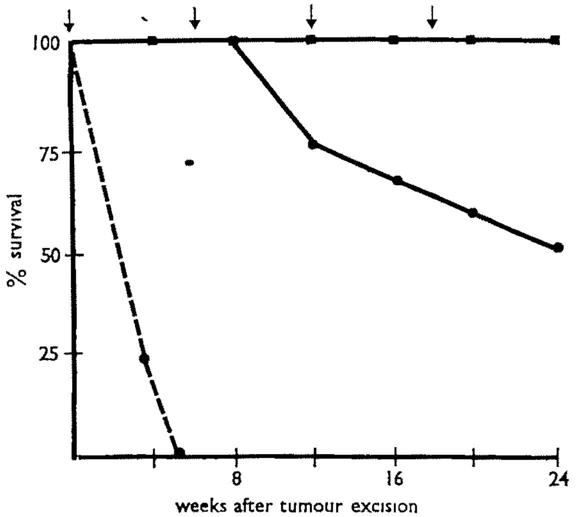

Fig. 3. The effect of NED 137 on recurrence after excision when administered every 6 weeks for 24 weeks. Untreated control animals (● — — — ●) showed recurrence and died by 5 weeks after excision. Fifty per cent of animals treated with a single dose of NED 137 (●——●) were dead from recurrent local tumour at 24 weeks after excision. Animals that received four consecutive doses of NED 137 (■——■) at 6-weekly intervals (↓) remained tumour-free. ($n = 60$ for each group.)

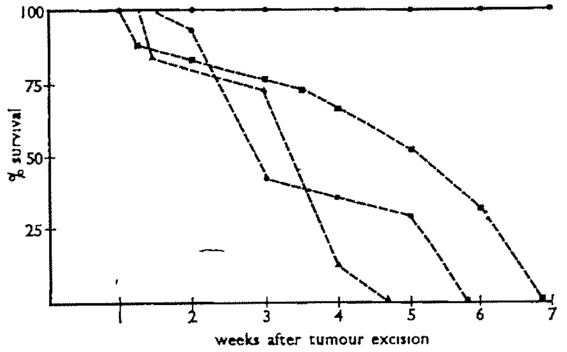

Fig. 4. The effect of NED 137 (●——●) compared with no treatment (▲), BCG (● — — — ●) and *C. parvum* (■) on tumour recurrence and survival. ($n = 10$ for each group.) (For details of administration *see* text.)

animals showed a marked increase in their capacity to destroy labelled tumour cells. *Table I* gives data obtained when cells or serum from cured animals were transferred to normal F344. The capacity to cause a significant degree of tumour cell lysis was transferred to normal animals in the 'cured' serum. Moreover, the serum component responsible for this increased destruction was precipitable by 40 per cent $(NH_4)_2SO_4$.

The efficacy of three adjuvant therapies—NED 137, *C. parvum* and BCG—on survival after tumour excision is compared in *Fig.* 4. It is apparent that NED 137 is markedly superior in prolonging survival after excision when compared with BCG or *C. parvum.*

Discussion

It should be possible to develop an effective immune response to tumour-specific antigens; however, it is exceptional to achieve this. A variety of hypotheses have been proposed to account for this inconsistency. It is apparent that both specific and non-specific suppression of the immune system can occur in the course of tumour development. It has been suggested that blocking factors in serum—either soluble tumour antigen or antigen-antibody complexes—interfere with potentially cytotoxic T cells capable of destroying tumour cells (Sjögren et al., 1971; Baldwin et al., 1973). Recent assessment of these findings suggests that these blocking factors could be non-specific.

Recently, particular emphasis has been placed on thymus-derived specific suppressor cells which are capable of suppressing an anti-neoplastic reaction, and manipulations to eliminate suppressor T cells have been examined. In these cases an enhanced response to the tumour antigen has been observed (Falk et al.,

Table I: ESTIMATION OF *IN VIVO* LYSIS OF ^{51}Cr-LABELLED TUMOUR CELLS

Treatment	Cpm/g (mean±s.e.mean)	Index
Nil	1362±41	1·00
FBCa	1321±78	0·97
NED	1348±85	0·99
FBCa+NED	572±61	0·42*
Transfer of:		
Normal cells	1268±39	0 93
Normal serum	1346±74	0·99
Cured cells	1294±62	0·95
Cured serum	898±28	0·55*
Cured serum precipitate	885±35	0·64*
Cured serum supernatant	1267±63	0·93

* $P<0·001$.

Animals with tumour only or NED 137 only showed no difference of recognition and destruction of tumour cells as compared with untreated rats. Tumour-bearing animals treated with NED 137 showed a significant increase in the destruction of tumour cells. Transfer of 'cured' serum to normal animals was able to effect a similar increase in tumour cell destruction. Comparable lysis of tumour cells was affected by the ammonium sulphate precipitate of the 'cured' serum but not from the supernatant or by the cells from 'cured' animals. ($n=5$ for each group.)

1978). It should be possible to obtain an effective anti-tumour response if a particular subpopulation of lymphoid cells could be stimulated selectively, thereby circumventing the T-cell system and, in particular, its suppressor component. The most likely candidate for B cell stimulation would be polyclonal activators as described by Möller (1977). These substances are B cell mitogens and stimulate B cells to effect enhanced antibody production. However, polyclonal activators can lead to the development of auto-antibodies (Primi et al., 1977).

NED 137 can enhance the number of antibody producing cells to non-allogeneic particulate antigens *in vivo*. No *in vitro* mitogenic effect was detectable and no auto-antibody has been demonstrable after *in vivo* use (Falk et al., 1979).

It is apparent from these studies that this polymer can promote a dramatic anti-tumour response. This response is transferred to normal animals by the serum of animals treated with NED 137. In treated animals, significant retardation of tumour growth and prevention of metastases is achieved. Toxicity experiments have shown that NED 137 has no acute or chronic toxicity in experimental animals. On this basis, a phase I study of advanced gastrointestinal malignancy was initiated in February 1979. No toxicity has been observed to date and early results from this study are promising.

In conclusion, a new polymer capable of specific stimulation of the immune response has been developed. As it is just one compound representing a family of polymeric compounds, it should be considered as the prototype of immune stimulants which specifically activate subpopulations of the immune system.

The effect of epidural analgesia on postoperative sodium balance

N. MENZIES GOW AND J. P. S. COCHRANE*

SUMMARY

The effect of a high epidural blockade on postoperative sodium (Na) retention has been studied in 8 patients undergoing cholecystectomy, with a further 8 patients, who received conventional anaesthesia and analgesia, acting as a control group. Preoperatively, all the patients received 90 mmol of Na per day and were in Na balance at the start of operation; this intake was continued for 48 h after the operation by intravenous infusion, and the epidural blockade was maintained with regular supplements of bupivacaine throughout. In addition to urine Na excretion and blood pressure changes, plasma levels of aldosterone, cortisol, renin activity and glucose were measured at appropriate intervals.

The Na retention in both the epidural and control groups was the same (139 mmol and 135 mmol respectively at 48 h), but there were significant differences in the measurements of all the other factors. It is concluded that the epidural was providing effective blockade, but that the factors which cause Na retention were not affected by the epidural blockade. These results are at variance with another study of the effect of epidural blockade on postoperative Na retention (Bevan, 1971), and the possible reasons for this are discussed.

SODIUM (Na) retention is one of the most constant features of the metabolic response to surgery, with approximately two-thirds of any postoperative Na intake being retained 48 h after a major operation. The cause of this Na retention is still unclear, but it seemed that an important advance in our understanding might have been made when Bevan (1971) reported that postoperative Na retention was abolished if a high thoracic epidural blockade was given. Bevan's study was carried out on 18 male patients undergoing vagotomy and pyloroplasty; all received a general anaesthetic and 8 were given, in addition, an epidural block, maintained for 48 h, from the fourth to the twelfth thoracic segments; 6 of the epidural group had a net Na loss over this 48 h, although their water balance was the same as the control group.

Although this reported effect of epidural analgesia has not been re-examined until now, many other studies of the effects of epidural blockade in the perioperative period have been carried out; it has been shown that an epidural block will delay the plasma cortisol response to surgery (Lush et al., 1972; Gordon et al., 1973; Cosgrove and Jenkins, 1974), will diminish the usual rise in blood glucose (Bromage et al., 1971; Brandt et al., 1976; Madsen et al., 1977), reduce the negative nitrogen balance (Brandt et al., 1978) as well as affecting the initial postoperative changes in fibrinolysis (Engquist et al., 1976). Thus it seems that epidural blockade may have a fundamental effect in modifying many of the metabolic and endocrine responses to surgery, possibly by interrupting painful stimuli from the operation site. However, Bevan's later explanation (Bevan, 1973) of the effect of epidural blockade on Na retention was that it was due to blocking of the sympathetic outflow to the kidney, rather than pain impulses from the wound.

This present study was designed to re-evaluate the effect of epidural blockade on postoperative sodium retention. Two groups of patients each received a standard general anaesthetic but one group was given a high epidural blockade in addition, maintained for 48 h. As well as following the Na balance, measurements were made of plasma cortisol and glucose changes to assess the effectiveness of the nerve block, and of the plasma aldosterone and renin changes to obtain further information concerning their possible role.

Patients and methods

Patients undergoing elective cholecystectomy were studied, and were excluded from the study if they had had any recent acute inflammation of the gallbladder, if they had any cardiovascular, endocrine or renal disease or if they were unwilling to give their informed consent to the study.

For 3 days before the operation the patients were given a diet containing 90 mmol each of Na and K daily, for accuracy low salt foods being supplemented with Slow-Na and Slow-K tablets, the last of any such supplements being given 24 h preoperatively. Urine collections were carried out over this period and patients were excluded from the study if their urinary Na output on the day before operation differed by more than 30 mmol from the intake on this day. The study was terminated when 16 complete investigations (8 in the control and 8 in the epidural group) had been achieved.

All operations started at approximately 0900 h. Premedication, usually methadone 10 mg and atropine 0·6 mg, was given at 0730 h and general anaesthesia induced at 0830 h with thiopentone; a muscle relaxant (usually d-tubocurarine, occasionally supplemented with suxamethonium) was given, the vocal cords were sprayed with local anaesthetic and an endotracheal tube passed. The patients in the epidural group then had a Lee Tuohy epidural cannula inserted into the T7–8 interspace and an epidural catheter passed, blockade being carried out with 10 ml of 0·5 per cent bupivacaine, the start of the operation being delayed 20 min to allow the bupivacaine to act. Blood pressure was measured at frequent intervals in all patients. Blood loss during the operation was measured by swab weighing.

At the start of operation an intravenous infusion was set up and all patients received, in each 24-h period, 3 l of water, 90 mmol of Na and 120 g of glucose in the form of 3 l of one-fifth normal saline in dextrose 4·5 per cent. No potassium was given and no oral fluids were allowed during the first 48 h after operation.

Postoperatively, analgesia in the epidural group was maintained for 48 h by injections of bupivacaine 0·5 per cent into the epidural catheter so that the band of analgesia extended from T4 to T12 dermatomes throughout this period. No difficulty was found in keeping all 8 patients completely pain-free, and although all of them had a fall of blood pressure following blockade no special corrective action was needed in any of them. Patients in the control group were given methadone 10 mg p.r.n. for analgesia, and patients in both groups were kept in bed throughout the 48 h study period. None of

the patients developed fever or any other complication in the postoperative period. No patient had a nasogastric tube passed and none had any significant extrarenal losses.

Urine was collected from all patients by bladder catheter which was passed immediately after induction of anaesthesia, and the urine volume, Na and K concentrations measured. Blood samples were collected via a plastic cannula inserted into a cubital fossa vein after the premedication had been given; samples were drawn at 0825 h, 0835 h (immediately after induction of general anaesthesia), 0900 h, 0930 h, 1000 h, 1030 h, 1100 h, 1200 h, 1400 h, 1800 h on the operation day, at 0830 h, 1200 h and 1800 h on the first postoperative day and at 0830 h on the second postoperative day. On each of these samples the following measurements were made: haematocrit (Hawkesley microhaematocrit); plasma proteins (Vickers auto analyser); Na and K concentrations (Vickers auto analyser); plasma aldosterone (radioimmunoassay by a modification of the method of Jowett et al., 1973); plasma renin activity (Menard and Catt, 1972); plasma cortisol (Corning cortisol radioimmunoassay kit); plasma glucose (Vickers auto analyser). The aldosterone, renin and cortisol assays had an interassay variability of 8, 2–9 and 7 per cent respectively, and an intra-assay variability of 6, 2–3 4 and 5 per cent. The total blood taken for analysis over the 48-h period was 160 ml in each patient. Apart from the Vickers auto analyser, all analyses were carried out in duplicate. The significance of the data was analysed by means of the Wilcoxon rank test.

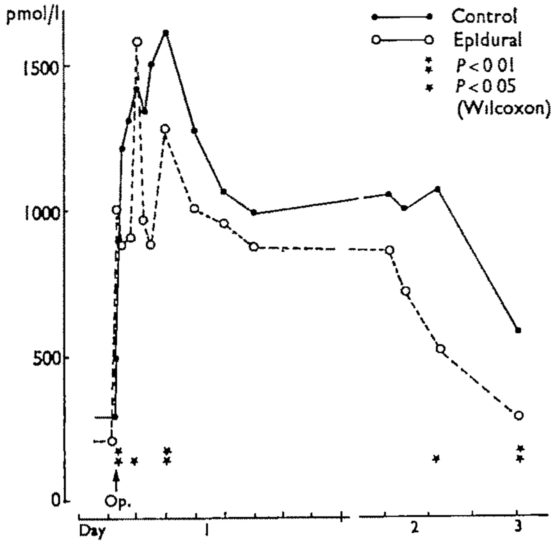

Fig. 4. Plasma aldosterone changes.

Results

Details of the patients in the two groups are shown in *Table I;* both groups are similar in median age, weight, height, duration of operation and operative blood loss.

Plasma cortisol (Fig. 1)

In the epidural group the cortisol response was delayed, the 0900 h, 0930 h and 1000 h samples being

significantly lower than those in the control group ($P<0{\cdot}01$ in each case). After this initial difference both groups had similar responses, both rising to a peak of between 6 and 7 times the basal preoperative concentration.

Plasma glucose (*Fig. 2*)

The median value of the epidural group was less than that of the control group at each sampling time after the start of operation, and although there was no significant difference between the groups at any one sampling time, the difference in median values over the whole period is significant on the sign test ($P<0{\cdot}05$).

Blood pressure (*Fig. 3*)

Although there was a fall in pressure in all patients studied, this fall was considerably greater in the epidural group, the pressures here being significantly lower than in the control group from just after the epidural was established until the end of the study period.

Sodium balance (*Table II*)

Both groups retain just over two-thirds of their Na intake at 48 h.

Plasma aldosterone (*Fig. 4*)

In the epidural group the initial response was more abrupt, and was significantly greater than in the control group just before the skin incision was made. Also the peak response occurred earlier in the epidural group, at the 1000-h sample (a 7·5-fold increase in median values) whereas the peak occurred at the 1200-h sample in the control group (a 5·4-fold increase). Over the remainder of the study period the response was smaller in the epidural group.

Plasma renin (*Fig. 5*)

The response was more abrupt in the epidural group, the values for the 0835-h and 0900-h samples being significantly higher than in the control group: the peak response on the operation day occurred later in the epidural group (a 2·9-fold rise at the 1400-h sample) than in the control group (a 2·5-fold rise at the 0930-h sample). The differences between the groups were not significant after the operation day.

Discussion

Before comparing the Na excretion results in our two groups of patients, it is necessary to determine that the epidural blockade was in fact effective throughout the study period. Clinical observations suggested that this was the case, because as soon as the patients recovered consciousness after the operation careful skin testing was carried out, and the band of analgesia was maintained from the T4 to T12 dermatomes by giving additional bupivacaine. Further evidence that the epidural blockade was effective is provided by the blood pressure readings and the plasma glucose and cortisol changes. The blood pressure in the epidural group was significantly lower throughout the period of study. The cortisol response was delayed in the epidural group, and although it was only delayed for a few hours, this result is very similar to that found in other studies (Lush et al., 1972; Gordon et al., 1973; Cosgrove and Jenkins, 1974); similarly the suppression of the hyperglycaemic response is very similar to that found by other workers (Bromage et al., 1971; Brandt et al., 1976; Madsen et al., 1977). On the basis of this evidence it seems reasonable to conclude that there was an effective blockade throughout the period of study.

The results show that there was no difference in Na balance in the two groups of patients, although there were slight, but significant, differences in the changes in plasma levels of renin and aldosterone; the greater rise of plasma renin in the epidural group was probably caused by the greater fall of systemic blood pressure in this group.

Our Na balance results are at variance with those of Bevan (1971). The reason for this is not immediately apparent. In that Bevan found a difference between his two groups of patients whereas we did not, it might be argued that in our study the epidural blockade was not effective. However, for the reasons given we believe that in our patients the epidural was effective. There are many differences in the methods used in the two studies. In our study the same fluid intake of approximately 2·8 mmol Na kg^{-1} 48 h^{-1} was used in all patients; from the diagram Bevan gives showing Na balance it would appear that his intakes ranged from 1·3 to 7·0 mmol Na kg^{-1} 48 h^{-1}, and fluids were given at different rates during and after the operation. There is also an important difference in the calculations of the Na balance since Bevan's Na output data include renal and gastrointestinal losses, but our patients had no significant extrarenal losses.

Other differences between the two studies are that Bevan's patients were males undergoing vagotomy and pyloroplasty whereas most of our patients were female and were undergoing cholecystectomy. Furthermore, all our patients were maintained on the same Na intake before surgery and were in Na balance at the start of the operation; in our patients the epidural blockade was maintained with plain bupivacaine whereas Bevan used bupivacaine with adrenaline. Bevan gives no details of whether his control group of patients was kept to the same degree of immobility and bed rest as the epidural patients, nor of the blood pressure changes in his two groups. However, in spite of these differences in methods used we are unable to explain the fundamental differences in the Na balance in these two studies.

In conclusion, in this present study high epidural blockade was found to have no effect on Na retention in patients undergoing uncomplicated cholecystectomy and receiving 90 mmol of Na daily; confirmation was found, however, of the delay of the cortisol response and reduction of the hyperglycaemic response to surgery by the epidural.

Acknowledgements

We are grateful to Drs I. Verner, J. Hulf and G. Grundy for their skilled administration of anaesthesia to these patients, to our ward sisters for their collaboration in the study, to Mrs N. Payne who performed the renin assays and to the staff of the Courtauld Institute of Biochemistry for their help in some of the estimations. We are also indebted to Professor L. P. Le Quesne for his advice and encouragement.

Multi-element analysis of the living body by neutron activation analysis—application to critically ill patients receiving intravenous nutrition

GRAHAM L. HILL, RODERICK F. G. J. KING, ROSS C. SMITH,
ALAN H. SMITH, CLEMENT B. OXBY, ALI SHARAFI
AND LEWIS BURKINSHAW*

SUMMARY

Neutron activation analysis has been used to determine the total content in the body of N, K, Na, Cl, P and Ca in 25 critically ill surgical patients before and after a 14-day course of intravenous nutrition. Muscle elemental composition was also determined in these patients at the same time as the total body analysis.

Over the 14-day period of intravenous feeding the total body contents of all the measured elements increased (2–9·7 per cent) but only the increase in K was statistically significant. Muscle chemistry suggested an intracellular K depletion which was corrected over the study period. The results of the total body multi-element analysis were interpreted to show a mean gain of 1·25 l of extracellular fluid and 0·51 l of intracellular fluid and direct measurement of total body water suggested that this interpretation was probably valid.

The first application of the technique to patients with nutritional and metabolic problems has quantified the weight gained by two body compartments during a 2-week period of intravenous nutrition. Its further application should help to solve a number of nutritional and metabolic problems in clinical surgery.

MANY hospital patients have abnormalities of body composition as a result of disease, trauma or sepsis. If the causes of these abnormalities are to be investigated it is important to be able to study the body composition of sick patients in as much detail as possible.

Traditional techniques for studying gross body composition, such as the measurement of body density by underwater weighing, are often unsuitable for clinical use. Dilution techniques for measuring body spaces can be used clinically, and give valuable information, but in at least some cases there is doubt as to what proportion of the total space is exchangeable (Chamberlain et al., 1968; Boddy et al., 1973).

In recent years, a new technique has been introduced which makes it possible to measure the total body contents of several elements. The technique is *in vivo* neutron activation analysis (Anderson et al., 1964). The body is irradiated with fast neutrons, some of which collide with nuclei of atoms in the body. Nuclear reactions then take place, and the reaction products are often radioactive nuclei. As they decay, these nuclei emit penetrating gamma rays which may escape from the body to be detected by external radiation counters. The energies of the gamma rays are characteristic of the nuclei which emitted them, and the resulting gamma ray spectrum can be analysed to give the body contents of several elements.

We have developed this technique into a clinically acceptable procedure which gives the body contents of N, Na, Cl, P and Ca as outlined above, and the content of K by virtue of its natural radioactive constituent, ^{40}K (Burkinshaw, 1978). The method appears capable of giving valuable new information about body composition in a variety of diseases, but its true value can be established only by its performance in actual clinical investigations. Therefore, over the past year, we have added it to our clinical procedures, and we now report our initial results on a group of 25 patients receiving intravenous nutrition.

Patients and methods

Clinical details of the 25 patients are given in *Table 1*. They were selected as follows: during 1978, 52 critically ill surgical patients were referred for intravenous feeding. All were studied according to the protocol described below. Of those who received an uninterrupted 14-day course of intravenous nutrition and gained wieght, 25 consented to muscle biopsy. These are the patients included in this report.

Intravenous nutrition was given for at least 15 days through a catheter placed in the superior vena cava according to the technique of Dudrick et al. (1970). The nutrient solution was a mixture of synthetic amino acids and dextrose with minerals and vitamins: equal volumes of Freamine II (McGaw Laboratories) and 50% dextrose to which 40–50 mmol of sodium, 20–40 mmol of potassium, 8–15 mmol of magnesium and 12–18 mmol of phosphorus were added per litre. Each 1000 ml of solution gave 42·5 gN and 1006 kcal. There were no complications attributable to the course of intravenous nutrition in any of the patients.

Vitamins were given as one daily ampoule of a multivitamin preparation (Multibionta, Merck Laboratories) and appropriate intramuscular doses of folate, vitamin K and vitamin B_{12}. The group received an average ($\bar{x} \pm$ s.d.) of 45·6 ± 11·3 kcal kg^{-1} d^{-1} and 0·30 ± 0·08 gN kg^{-1} d^{-1} (*Table 1*).

Body weight, body fat, total body water and the total body contents of N, K, Na, Cl, P and Ca were measured before intravenous nutrition and again 14 days later while intravenous nutrition was continuing. At the same times muscle and venous blood samples were taken and the concentrations of N, K, Na and Cl were determined in the extracellular and intracellular fluid of muscle.

Skinfold thicknesses were measured at the biceps, triceps and subscapular sites, using Holtain skinfold calipers. Three measurements were made at each site and the mean values used to calculate total body fat from the equations of Durnin and Womersley (1974). Total body water was calculated from the dilution in the body of 100 μCi of tritiated water given intravenously. A plasma sample was taken between 3 and 5 h after injection and duplicate aliquots of the plasma sample and appropriate standards were added to a NE260 (Nuclear Enterprises (GB) Ltd) scintillator and measured on a liquid scintillation counter. Pre-dose background plasma samples were taken before the second administration for the measurement of the remaining radioactivity.

Total body N, Na, Cl, P and Ca were measured by *in vivo* neutron activation analysis. Each patient was irradiated bilaterally with 14 MeV neutrons from a sealed tube neutron generator. Patients 3, 5, 16, 18, 19, 20, 21, 23 and 25 received a total surface dose equivalent (neutrons and γ-rays) of

500 mrem, and the remainder received 50 mrem. The neutrons generate in the body short-lived radioisotopes which are specific for various body elements, and which decay with the emission of γ-rays of characteristic energies. The radiation emitted from the patient is measured in a whole body radiation counter and the complex spectrum analysed by a least squares technique to give the counting rates due to: ^{13}N (a short-lived reaction product of N), ^{24}Na, ^{38}Cl, ^{28}Al (which comes from P), ^{49}Ca and ^{40}K, which is a naturally occurring radionuclide of potassium. These counting rates are corrected for decay and variations in output of the neutron generator and the total body contents of the elements are calculated by multiplying the counting rates by appropriate calibration factors.

The precision of the measurements is a function of the radiation dose. *Table II* shows the coefficient of variation (%) obtained for each element when an anthropomorphic phantom was irradiated and measured five times at the two dose levels used in this study.

The accuracy appears to be satisfactory for clinical studies. At the higher dose the difference between the mean measured quantity of an element in the phantom and the true content ranged from 0·7 per cent for sodium to 4·3 per cent for calcium.

It would clearly have been preferable to have measured all the patients at the higher dose. However, in earlier stages of our work, we measured only potassium and nitrogen, for which the smaller dose is adequate, and this study was carried out during the period of transition to multi-element analysis using the higher dose.

The muscle samples were taken from the vastus lateralis muscle approximately 14–16 cm above the knee. Local anaesthetic (lignocaine plain, 2 per cent) was injected subcutaneously and a 1-cm incision was made into the skin and muscle fascia. The procedure of plunging the needle through the incision and sampling a piece of muscle took less than 20 s. The tissue was immediately placed in a clean plastic tube and taken to the laboratory where it was placed on a plastic sheet and rapidly freed of visible fat and connective tissue by dissection. The sample was then rolled to remove surface water, placed on aluminium foil and weighed every 15 s on a Cahn electrobalance. The rate of water loss was used to calculate by extrapolation the weight of the sample when it was removed from the container. The sample was frozen (−20 °C), freeze dried for approximately 20 h and dried to a constant weight. The water content was calculated from the weight loss. Fat was extracted from the dried sample into distilled petroleum ether (40–60) (Flear and Florence, 1961), the samples were dried and reweighed and the fat content was calculated from the weight loss.

The pieces of fat-free dry muscle were ground in an agate mortar and the powder was divided into two weighed samples, one, the larger, for electrolyte analysis and the other for nitrogen determination.

Electrolyte estimation

An accurately weighed portion of muscle powder (about 1–2 mg) was dissolved in 250 μl of 1N nitric acid and 100 μl of the solution were transferred to a small plastic pot and 20 μl of borate solution (Cotlove, 1963) were added. To the remainder of the solution (150 μl), 450 μl of water were added and two 250-μl portions of this diluted solution were removed for analysis of sodium and potassium. Sodium and potassium were measured with an EEI dual channel flame photometer, chloride was measured, after neutralization of the borate solution with 30 μl of 7·5 N nitric acid, by titration with silver nitrate using silver and mercurous sulphate electrodes as described by Bergstrom and Hultman (1974).

Nitrogen determination

Nitrogen was measured by sulphuric acid oxidation of organic nitrogen into ammonium ions which were estimated colorimetrically by an auto analyser method (Ferrari, 1960).

Water partition

The sample content of chloride was used to partition total water between the intra- and extracellular compartments (Bergstrom and Hultman, 1974).

Blood analysis

Venous blood, obtained on the same day as the biopsies, was analysed for sodium, potassium, chloride, bicarbonate, calcium, phosphate, urea, albumin and total protein.

Analytical precision

Analytical precision was estimated by taking 10 aliquots weighing between 1 and 2 mg from a solution containing ions at concentrations similar to those in muscle. The coefficients of variation were 2·3 per cent for sodium, 7·4 per cent for chloride, 2·1 per cent for potassium and for a powdered sample 8·3 per cent for nitrogen.

Table II: COEFFICIENTS OF VARIATION (%) OBTAINED WHEN AN ANTHROPOMORPHIC PHANTOM WAS IRRADIATED AND MEASURED FIVE TIMES

Values are mean ± s.e. mean.

Results

The 25 patients gained an average (mean ± s.e.mean) of 2·62 ± 0·54 kg of bodyweight ($P<0{\cdot}001$); 0·55 ± 0·17 kg of body fat ($P=0{\cdot}003$) and 2·33 ± 0·55 l of water ($P<0{\cdot}001$) over the 14-day study period. The increases in the total body contents of N, K, Na, Cl, P and Ca are shown in *Table III*. *Table IV* shows the concentrations of N, K, Na and Cl in extracellular (ECF) and intracellular fluid (ICF) of skeletal muscle before and 14 days after intravenous nutrition.

The increase in total body K was associated with an increase in the concentration of potassium in both ECF (3·75 to 4·20 mmol/l, $P<0{\cdot}001$) and ICF (138·5 to 167·3 mmol/l, $P<0{\cdot}005$), but the concentrations of N, Na and Cl were not changed significantly by IVN. The changes in total body N, Na and Cl therefore reflect changes in the volumes of ECF and ICF. Let ΔE, ΔI be the mean changes in these volumes, let ΔN, ΔNa, ΔCl be the mean changes in total body N, Na and Cl and let $[N]_E$, $[Na]_E$, $[Cl]_E$ and $[N]_I$, $[Na]_I$, $[Cl]_I$ be the mean values, estimated from all the muscle samples, of the concentrations of the elements in ECF and ICF. These quantities are related by the equations:

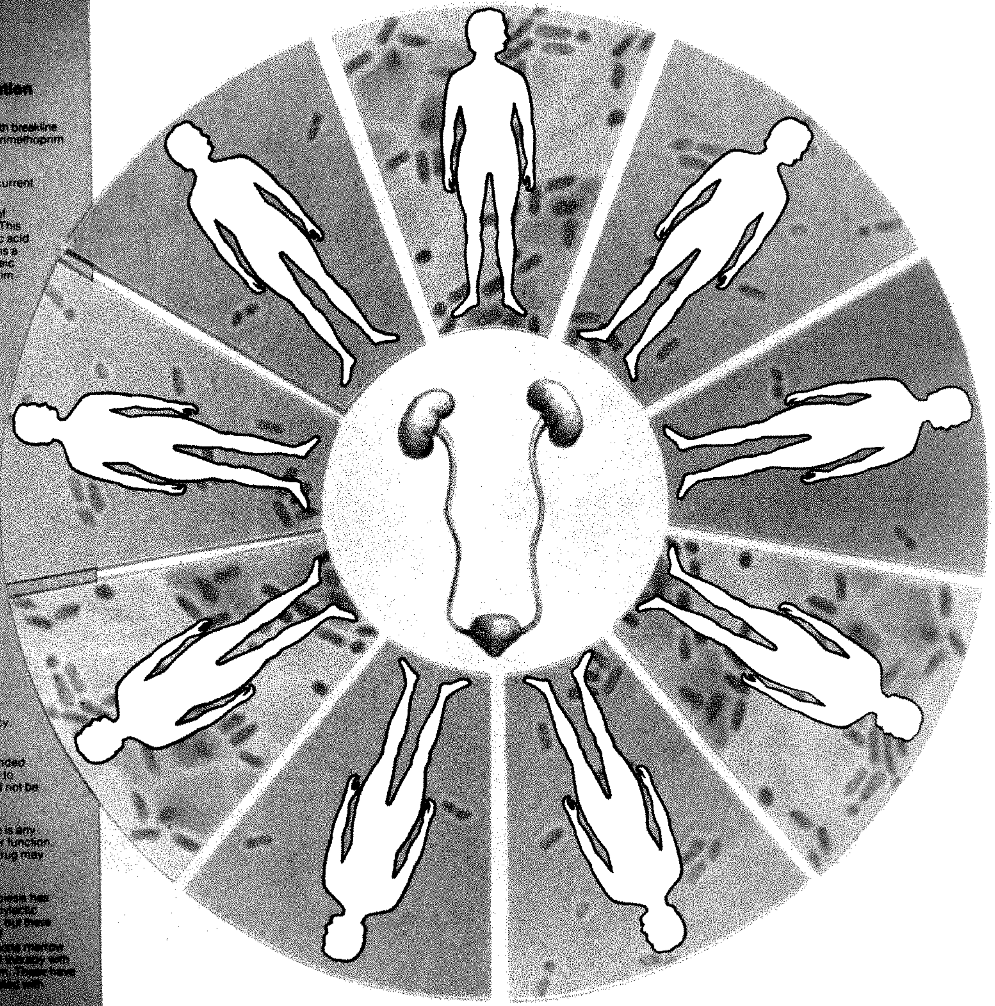
TRIMOPAN

trimethoprim

effective prophylaxis in recurrent urinary tract infection



Prescribing Information

Presentation
[illegible] diameter with breakline on reverse, each containing trimethoprim B.P. 100mg

Uses
Long-term prophylaxis of recurrent urinary tract infection.

Trimethoprim is an inhibitor of dihydrofolic acid reductase. This enzyme converts dihydrofolic acid to tetrahydrofolic acid which is a precursor of desoxyribonucleic acid. The effect of trimethoprim on folic acid synthesis is 50,000 times weaker in human cells than in bacterial cells. Trimethoprim has a range of activity very similar to that of sulphonamides but, *in vitro* most organisms show a far higher sensitivity to trimethoprim. The only coliform bacterium resistant to trimethoprim is Pseudomonas, whereas enterobacter, E. coli, Proteus and Klebsiella are trimethoprim-sensitive. Likewise trimethoprim is suitable for the therapy of Streptococcus faecalis infections. Gonococcus is trimethoprim-resistant.

Dosage and administration
Adults: For the prophylaxis of recurrent urinary tract infection, one tablet each night before bed.
Children: Paediatric dosage for prophylaxis has not been established.

Contra-indications
Serious hepatic or renal dysfunction, folate deficiency, blood dyscrasias.
Although there is no clinical evidence that the recommended dosage of Trimopan is harmful to the foetus, Trimopan should not be used in pregnancy.

Precautions
[illegible] when there is any [illegible] of kidney or liver function [illegible] accumulation of the drug may [illegible]

[illegible]

Highly active against common urinary pathogens

"The most common gram-negative bacilli, E. coli, Proteus and Klebsiella are sensitive to trimethoprim . . . Pseudomonas is resistant."(1)

Extensive clinical experience – low relapse/reinfection rates(1)

"[Trimopan] . . . has been used for more than 600,000 months of treatment, i.e. 50,000 patient years."(1)

Low incidence of resistance

"The percentage of trimethoprim-resistant strains in clinical practice has not increased remarkably during recent years."(1)

Well tolerated

". . . trimethoprim alone appears the safest of all drugs [tested] against urinary tract infection."(1)

Convenient once daily dosage

Simply – one 100mg tablet nightly.

for recurrent U.T.I.

Rx Trimopan 100mg
1 tablet at night (28)

As sens
Hotlips
and just
as
tough.

As they have to be in the real world.

Most Surgeons know that Regent Dispo Surgeons' Gloves from LRC are extra tough and yet extra sensitive, with a uniquely roughened surface for extra grip.

And they come in a range of sizes which help make them the best fit around. If fact they are the gloves specially developed for British Surgeons to their specific requirements.

Which makes them all in all a most superior glove, a little like the lady from M.A.S.H.

Benign Breast Disorders

3 studies on Danol

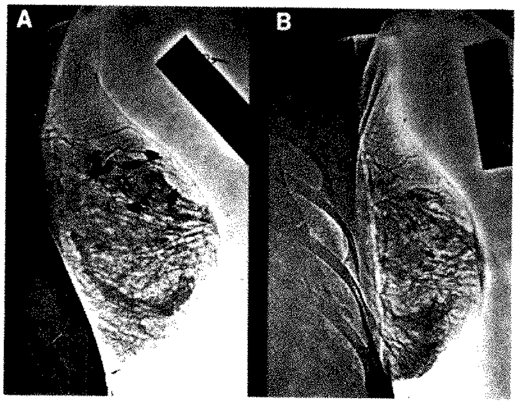
1. "...a marked improvement in both objective and subjective symptoms in 87.5% of patients studied."

(Study of 40 patients given Danol for up to 6 months. Obstet. Gynec. 1976, 48: 93.)

---

2. 75.8% "...experienced complete relief of subjective discomfort with disappearance of clinical signs."

(Study of 58 patients given Danol for between 74 and 310 days. Am. J. Obstet. Gynec. 1977, 127: 130.)



Xeromammograms of patient with intense fibrocystic disease (A) showing marked reduction in breast size and cystic area (B) after 6 months on Danol

---

3. "...a significant decrease and elimination of breast pain and tenderness ...and elimination of nodules and lumpy areas..."

(Preliminary report on open study of 260 patients given Danol for 4 to 6 months. J. int. med. Res. 1977, 5 (Suppl. 3) 101-108.)

Danol
danazol

antigonadotrophic agent without oestrogenic or progestogenic activity

Danol (danazol 200 mg) PL 0071/0095. Bottles of 100 capsules. Basic NHS cost of one day's treatment £1.42 (3 capsules). **Danol-½** (danazol 100 mg) PL 0071/0094. Bottles of 100 capsules. Basic NHS cost of one day's treatment 72p (3 capsules). **Dosage** Adults 200-800 mg daily. See Data Sheet for details. **Contra-indications** Pregnancy. **Precautions** 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop. **Side Effects** Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control. Danol is a trade mark. Clinical reports and full prescribing information available on request from **Winthrop Laboratories**, Surbiton-upon-Thames, Surrey.

WINTHROP

$$[N]_E \Delta E + [N]_I \Delta I = \Delta N \quad (1)$$
$$[Na]_E \Delta E + [Na]_I \Delta I = \Delta Na \quad (2)$$
$$[Cl]_E \Delta E + [Cl]_I \Delta I = \Delta Cl \quad (3)$$

Since there are three equations but only two unknowns (ΔE, ΔI), and since ΔN, ΔNa and ΔCl are measured with error, the equations have no unique solution, but estimates of ΔE and ΔI can be calculated by the method of weighted least squares (Topping, 1962). The calculation gives the increase in ECF as 1·25 ± 0·67 l and the increase in ICF as 0·51 ± 0·52 l. The sum of these (1·76 l) agrees with the mean gain in total body water measured by tritium dilution (2·33 ± 0·55 l).

Discussion

In this first application of multi-element *in vivo* neutron activation analysis to studies of critically ill surgical patients, the technique has made it possible to quantify the changes in two compartments of the fat-free mass. The results suggest that the technique will be of real value in the elucidation and treatment of difficult metabolic and nutritional problems. We have already used neutron activation analysis to measure total body nitrogen directly in a wide variety of very ill surgical patients (Hill et al., 1978; Collins et al., 1979) and the results obtained have given us valuable information on the tissue composition of the weight lost after surgery (Hill et al., 1978) and on the tissue composition of the weight gained with intravenous nutrition (Hill et al., 1979) and with an elemental diet (Yeung et al., 1979). It is not surprising therefore that this further extension of neutron activation analysis to surgical patients has yielded useful information.

Multi-element analysis of 25 ill patients receiving intravenous nutrition at the start of treatment and again 14 days later showed increases in all the elements measured over the study period, although the increase was statistically significant only for K. From the data, we estimate that ECF increased by 1·25 l and ICF by 0·5 l; the sum of these increases is in reasonable agreement with the increase in total body water measured directly, suggesting that the interpretation is probably valid.

It might be argued that, as Rudman and his colleagues (1975) have shown, similar information can be derived from detailed elemental balance studies. Neutron activation analysis is, however, a less laborious procedure, and has the great advantage that it is not subject to cumulative errors resulting from loss of excreta (Hegsted, 1976; Beisel, 1979).

The precision of the technique (*Table II*) is adequate for clinical use. Suppose, for example, that 15 patients are measured with a dose-equivalent of 500 mrem, at the beginning and end of a 14-day period, during which they gain 4 g of nitrogen per day (56 g total). Then the mean daily change can be estimated with a standard error of ± 0·5 gN (13 per cent); the smallest mean change which could be detected with 95 per cent confidence would be 1·1 gN per day. These figures are rather optimistic because the reproducibility of measurements made on patients may not be quite as good as those made on phantoms (*Table II*), and the standard errors of the measured mean changes will be increased by biological differences between patients, but they serve as a guide.

We suggest, however, that the great importance of multi-element analysis is not that it replaces balance techniques but that it measures directly the total body contents of the major elements. The measured contents are of interest in themselves, but it also seems likely that they can be used to determine the sizes of various body compartments. The concept of body compartments is not new (Reifenstein et al., 1945). The principal subdivisions are: protoplasm which is rich in N, K and P, ECF which contains Na and Cl, bone which contains Ca, P and Na and fat which contains C and H. The interpretation of total body changes in terms of changes in these body compartments by uncritically using fixed ratios of the predominant elements within a given compartment can, however, be quite misleading in very ill patients. In the present study, for instance, the average intracellular concentration of muscle K was lower than normal (King et al., 1978) and this was corrected over the 14-day period of intravenous nutrition. Therefore the measured gain in total body K of 9·7 per cent cannot be interpreted as a gain of protoplasm.

Clearly, a great deal of work remains to be done. We hope soon to extend the scope of the analysis by introducing measurements of total body carbon, hydrogen and oxygen, and we are studying the difficult problem of relating the results of the measurements to the size and condition of body compartments.

Acknowledgements

The development and application of the neutron activation analysis technique are supported by a Medical Research Council Programme Grant to the Department of Medical Physics. The muscle chemistry work is supported by the Yorkshire Regional Health Authority.

We are grateful to Professor D. Johnston, Professor R. E. Ellis and Professor D. B. Morgan for their advice and help with this project, to Miss D. W. Krupowicz and Mr K. Brooks, who carried out the neutron activation measurements, and to Miss R. A. Siwek, who assisted with data processing.

Abstracts

The Fourth Joint Meeting of the Surgical Research Society, the Society of University Surgeons and the European Society for Surgical Research, with the Surgical Research Society of Australasia, the South African Surgical Research Society and the Japanese Surgical Society, was held at the Nuffield Department of Surgery, University of Oxford, on 5, 6 and 7 July 1979 with Professor Herbert Duthie (President of the Surgical Research Society) in the Chair. The following papers were presented.

1. Cyclosporin A: effect and mode of action upon renal allografts in the dog and rat

W. P. HOMAN, M. FRENCH, KERYN A. WILLIAMS, P. MILLARD, T. G. DENTON, J. W. FABRE and P. J. MORRIS, *Nuffield Department of Surgery, University of Oxford, Radcliffe Infirmary, Oxford*

Cyclosporin A (Cy A), a new immunosuppressive agent, has been examined in dog and rat kidney allograft models. Experiments were designed to establish (1) optimal dosage, (2) optimal duration of treatment, (3) toxicity, (4) interaction with prednisolone, (5) mechanism of action and (6) effect on acute rejection. Kidney allografts between outbred dogs treated orally with Cy A at doses of 5 and 10 mg/d showed significant prolongation of survival with no histological evidence of rejection at day 7. Continued treatment, with the drug, however, did not prevent rejection, and was no more effective than a 14-day course at the same dose. The addition of prednisolone may augment the immunosuppressive effect. No evidence of nephrotoxicity or hepatoxicity was noted.

Treatment (daily)	No. of dogs
A. Cy A 10 mg/kg × 14 d	7
B. Cy A 5 mg/kg × 14 d	4
C. Cy A 2 mg/kg × 14 d	5
D. Cy A 10 mg/kg indefinitely	6
E. Prednisolone 1 mg/kg daily	6
F. Cy A 10 mg/kg indef. + pred.	6
G. Azathioprine + pred. (2 mg/kg) (1 mg/kg)	7
H. No treatment	4

Survival (d)	Median survival
A. 16, 17, 22, 28, 29, 36, 75	28
B. 16, 19, 22, 30	21
C. 7, 9, 9, 14, 18	9
D. 19, 22, 25, 47, (>8, >8)	24
E. 7, 7, 7, 7, 7, 8	7
F. 21, 24, >24, >29, (>7, >7)	>24
G. 9, 11, 13, 35, 45, 58, 72	35
H. 8, 8, 8, 9	8

Renal allografts from DA to Lewis rats, across a major histocompatibility barrier, survived indefinitely with no evidence of rejection, and again sharp dose–response effects were seen. The humoral response to the graft was measured by a ^{51}Cr release lymphocytotoxicity assay, and the cellular response by lymphocytic killing of ^{51}Cr-labelled thymocyte target cells. Cy A suppresses both the humoral and cellular responses to the allograft when used at optimal dosage. Even massive doses of Cy A, withheld until rejection of the graft was commencing, did not influence the course of the rejection.

Thus, Cy A is a powerful immunosuppressive agent in these models. It appears to act at the induction phase of the immune response to a renal allograft, abolishing both the humoral and cellular responses to the graft.

2. Postoperative pulmonary embolism: prevention by dextran or s.c. heparin?

U. F. GRUBER, T. BROKOP, B. EKLÖF, I. ERIKSSON, I. GOLDIE, L. GRAN, M. HOHL, T. JONSSON, S. KRISTERSSON, K. G. LJUNGSTRÖM, T. LUND, H. MAARTMAN MOE, T. SALDEEN, D. THOMSON, J. TORHORST, A. TRIPPESTAD and M. ULSTEIN, *Department of Surgery, Kantonsspital, CH-4031 Basel, Switzerland*

Both small doses of s.c. heparin as well as dextran 70 infusions have been shown to reduce the incidence of fatal pulmonary emboli as compared with no prevention. A prospective, randomized study in order to compare for the first time the two methods was initiated in 1976 with the following general surgical (S), orthopaedic (O), urological (U) and gynaecological (G) departments participating:

1. Kantonsspital, University of Basel (S, O, U, G—U. F. Gruber, M. Hohl, J. Torhorst)
2. Haukeland Sykehus, University of Bergen (S, O, U, G—L. Gran, H. Maartman Moe, A. Trippestad, M. Ulstein)
3. Sahlgrenska Sjukhuset, University of Göteborg (O—I. Goldie, T. Jonsson)
4. Lasarettet Helsingborg (S—S. Kristersson)
5. Lasarettet, University of Lund (S, U—T. Brokop, B. Eklöf, D. Thomson)
6. Lasarettet Danderyd, Stockholm (S—K. G. Ljungstrom)
7. Akademiska Sjukhuset, University of Uppsala (S, U—I. Eriksson, T. Saldeen)

The endpoint of the study was pulmonary embolism proved at autopsy. All patients were followed up for 1 month after the operation. Special attention was paid to the practical application and side effects of the two preventive methods.

We followed the protocol as it was applied in the heparin multicentre trial (Kakkar et al., 1975). Patients in the dextran group received 6 per cent Dextran 70 in saline (Macrodex) 3 × 500 ml: the first 500 ml being infused during operation, the second 500 ml on the evening of the operation day and the third 500 ml on the morning of the first postoperative day. All autopsy reports were evaluated by one pathologist (T. Saldeen).

A total of 4352 patients was admitted to the trial: 75 patients died during the first postoperative month, 38 in the dextran, 37 in the heparin group, the autopsy rate being 87 per cent in the dextran and 86 per cent in the heparin group. There were 5 fatal cases of pulmonary embolism in the dextran group and 3 in the heparin group. In 1 case in the dextran and in 3 of the heparin group the pathologist considered the pulmonary embolism to be contributory to death. There were 6 incidental findings of pulmonary embolism (e.g. pre-existing pulmonary embolism, microemboli), 2 in the dextran, 4 in the heparin group. Since the incidence of pulmonary embolism found at autopsy in both groups is about the same, it is concluded that both methods exert the same protective effect.

KAKKAR V. V., CORRIGAN T. P. and FOSSARD D. P. (1975) Prevention of fatal postoperative pulmonary embolism by low doses of heparin. *Lancet* **2**, 45–51.

3. Glomerulotubular sodium dynamics after supplemental albumin resuscitation

C. E. LUCAS, ANNA M. LEDGERWOOD and R. F. HIGGINS, *Department of Surgery, Wayne State University, Detroit, Michigan, USA*

Previous data from this laboratory demonstrated that albumin (Alb.), when added in a random fashion to a standard resuscitation regimen for hypovolaemic shock, causes renal sodium (Na) retention; the mechanism was not delineated.

Intrarenal Na dynamics, therefore, were analysed in 94 patients who received an average of 14·5 transfusions for shock; 46 patients received supplemental Alb. totalling 31 g during resuscitation and 150 g/d for 3–5 days. Renal plasma flow (C(PAH)), glomerular filtration rate (C(In)), Na and potassium (K) perfusion (Na-P and K-P), Na (Na-F) and K filtration (K-F), Na collecting duct flow (Na-CD), nephron reabsorption of Na (%Na-F) and K (%K-F), collecting duct reabsorption of Na (%Na-CD) and K excretion (KE-CD), and clearance of Na (C(Na)) and K (C(K)) were studied serially and compared by the Student *t* test.

Alb. increased serum Alb. levels (4·2 *v.* 2·9 g/dl), plasma volume (3895 *v.* 3579 ml), C(PAH), Na-P, and K-P (Table). In contrast, C(In) fell, thereby causing a significant fall in Na-F, K-F, and Na-CD (Table). The %Na-CD was greater in Alb. patients who, therefore, had a lower C(Na); increased %Na-CD paralleled a fall in KE-CD (Table).

	Alb.	Non-Alb.
C(PAH)* (ml/min)	466	411
Na-P* (mmol/l)	63·4	56·1
C(In)* (ml/min)	85	107
Na-F* (mmol/min)	11·9	14·5
Na-CD* (mmol/min)	1·8	2·2
%Na-CD* (mmol/min)	84	78
(KE/CD) (mmol/min)	0·12	0·14
C(Na) (ml/min)	1·45	2·4

Value expressed as mean; *indicates $P<0·05$.

Alb. causes a rise in perfusion but a fall in filtration of Na and K, possibly due to negative glomerulotubular Na feedback or increased oncotic pressure within the tuft. Further Na retention in the distal nephron due to NA-K exchange probably reflects a high inner medullary osmolality. This excessive Na retention promotes vascular overload with its important clinical implications.

4. Highly selective vagotomy for duodenal ulcer: the clinical results after 10 years

D. JOHNSTON and A. T. R. AXON, *University Department of Surgery and Gastroenterology Unit, General Infirmary, Leeds*

HSV for duodenal ulcer (DU) in man was first described 10 years ago (Johnston and Wilkinson, 1969). The clinical results after 10½ years are presented, attention being focused on the first 100 consecutive patients (80 M, 20 F, mean age 42, length of history 9 years; PAO, 43 mmol/h) who were operated on by one surgeon, assessed 'blindly' at a follow-up (FU) clinic each year and followed for 8·5 (7–10·4) years, 38 per cent of them were hypersecretors (PAO>45 mmol/h).

In 96 per cent of patients, pre- and postoperative BAO and PAO$_{\text{pg}}$, and postoperative PAO were measured. All patients with pain after HSV were endoscoped, but those without pain were not. Six patients died during FU, none of ulcer disease, 2 emigrated and of the remaining 92, 7 were lost to FU.

Operative mortality was nil. Lesser curve necrosis was not encountered. One patient required reoperation for stasis (now Visick grade 3). The insulin test (IT), 1 week after HSV, was Hollander negative in 93 patients and late positive in 3. Mean PAO$_{\text{I}}$ − BAO was 0 mmol/h and only 4 tests were Stempien positive. None of the first 50 patients had a 'positive' IT: no patient has developed recurrent ulceration (RU) after 8–10 years. Two patients (2 per cent) developed RU: both had late positive ITs. One is Visick 1 and one Visick 4. RU was suspected at one time or another in a further 8 patients, but OGD + barium meal ± laparotomy were negative. Dumping was noted in 2 per cent (all mild), diarrhoea in 3 per cent and bilious vomiting in 3 per cent (male patients). Four patients are currently Visick grade 4.

The use of HSV has eliminated dumping, diarrhoea and bilious vomiting as clinical problems. A 2 per cent incidence of recurrent ulceration is attainable. Hypersecretors do not need antrectomy, if the vagotomy is complete. Intraoperative testing, a stimulus to the trainee, is not essential.

JOHNSTON D. and WILKINSON A. R. (1969) Selective vagotomy with innervated antrum without drainage procedure for duodenal ulcer. *Br. J. Surg.* 56, 626.

5. ^{111}Indium-labelled autologous leucocyte scan: analysis of a new diagnostic tool in postoperative sepsis

NANCY L. ASCHER, D. H. AHRENHOLZ and R. L. SIMMONS, *Department of Surgery, University of Minnesota, Minneapolis, Minnesota, USA*

Intra-abdominal infection is difficult to diagnose in the patient who has recently undergone gastrointestinal surgery. Physical examination may be deceptive and the currently available diagnostic techniques are not uniformly accurate and are limited in scope. We have previously described a new scanning technique in the diagnosis of infection. The patient's peripheral polymorphonuclear granulocytes (PMNs) are separated and labelled *in vitro* with ^{111}Indium. The autologous labelled PMNs are reinjected i.v. and whole body scanning carried out in 24 h. Radioactivity is concentrated at sites of PMN accumulation, i.e. sites of infection and/or inflammation. This is the first study to analyse the accuracy of the procedure in the differential diagnosis of suspected intraperitoneal sepsis in patients following gastrointestinal surgery. Sixty-six scans were performed in 43 patients: 43 scans were negative; 37 of these proved to be clinically negative and represent true negative scans. The remaining 6 (9 per cent) scans proved to be false negative, i.e. the patients in fact had infection. Twenty-three scans were positive; 19 were truly positive, 2 (6 per cent) were false positives and 2 (6 per cent) were equivocal (representing clinical inflammation but no infection). Thus the overall accuracy of this non-invasive, relatively rapid diagnostic procedure was 85 per cent. This is certainly the single most accurate readily adaptable technique in the diagnosis and localization of covert sepsis in the surgical patient.

6. The release of vasoactive intestinal peptide during altered mid-gut blood flow

P. G. BATESON, K. D. BUCHANAN and T. G. PARKS, *Departments of Surgery and Medicine, The Queen's University of Belfast*

(*see* Volume 67, January 1980)

7. Serum prolactin levels in the Zollinger–Ellison syndrome

B. E. STABILE, E. P. PASSARO JUN. and H. CARLSON, *Surgical Service, VA Wadsworth Medical Center, Los Angeles, California, USA*

Human serum prolactin (PRL) levels were measured in 37 patients with proved Zollinger–Ellison syndrome (ZES). Eight patients had elevated levels (>12 μg/l in males and >21 μg/l in females). There was no correlation between serum PRL levels and serum gastrin levels, gastrinoma mass, or serum HCG levels.

Five of these eight patients had other evidence of MEA. In the remaining 3 patients, an MEA syndrome was evidenced only by the elevated PRL level. One of the 5 patients with obvious MEA developed visual field defects and radiographic evidence of sella turcica erosion. This was the only patient with an elevated PRL level (43 μg/l) known to have developed a demonstrable pituitary tumour. Studies over 4–5 years in 3 patients showed a tendency for serum PRL levels to increase modestly.

An elevated serum PRL level is a frequent finding in patients with ZES. While it is found most often in patients with obvious MEA syndromes, a number of patients may have high PRL levels without other evidence supporting multiglandular disease. Since levels tend to increase with time, and clinically significant pituitary tumours can develop, it is recommended that all patients with ZES have serial serum PRL determinations performed.

8. Are gastric prostaglandins regulators of gastric acid secretion?

R. BAKER, B. M. JAFFE, J. D. REED and C. W. VENABLES, *Departments of Surgery and Physiology, Universities of Newcastle upon Tyne, UK, and Washington University, St Louis, Missouri, USA*

We have previously demonstrated that at a constant rate of infusion of pentagastrin, histamine and insulin there are similar positive correlations between outputs of acid and immunoreactive PGE into gastric juice. To test the hypothesis that PFE may be involved in a local negative feedback mechanism for the control of acid secretion this relationship has been further studied in six conscious cats with gastric fistulas following incremental doses of pentagastrin (1–32 $\mu g\ kg^{-1}\ h^{-1}$)

and histamine (50–375 μg kg^{-1} h^{-1}) with and without flurbiprofen, a prostaglandin synthesis inhibitor. There was a significant linear acid secretory response to incremental doses of both pentagastrin and histamine ($r = 0{\cdot}981$, $P = 0{\cdot}018$); however, in neither experiment was the output of PGE (measured by radioimmunoassay) dose-dependent. Following a predose (0·2 mg/kg) and the simultaneous infusion of flurbiprofen (0·1 mg kg^{-1} h^{-1}), the acid secretory response to pentagastrin and histamine remained unchanged despite inhibition of gastric PGE output (>60 per cent).

Pentagastrin (μg kg^{-1} h^{-1})	[illegible]	2	4	8	16	32
PGE output pg kg^{-1} 15 min^{-1}						
	87	366	214	105	93	176
	±49	±60	±34	±19	±10	±26
Acid output μmmol kg^{-1} 15 min^{-1}						
	234	303	383	375	415	417
	±28	±23	±30	±36	±35	±29
Acid output after flurbiprofen μmol kg^{-1} 15 min^{-1}						
	239	300	367	402	368	367
	±34	±44	±51	±46	±35	±25

Histamine (μg kg^{-1} h^{-1})	50	125	250	375
PGE output pg kg^{-1} 15 min^{-1}				
	73	68	178	144
	±15	±12	±25	±36
Acid output μmmol kg^{-1} 15 min^{-1}				
	140	308	393	410
	±25	±34	±33	±46
Acid output after flurbiprofen μmol kg^{-1} 15 min^{-1}				
	168	320	417	443
	±32	±33	±35	±42

The failure of PGE to correlate with acid output in dose-response experiments and the lack of potentiation of acid secretion during inhibition of endogenous prostaglandin synthesis suggests that the proposed negative feedback mechanism involving PGE in gastric juice is incorrect.

9. Calcium infusion—a new provocative test for insulinomas

E. L. KAPLAN, A. H. RUBENSTEIN, R. EVANS, P. KLEMENTSCHITSCH and C. H. LEE, *Department of Surgery and Medicine, University of Chicago Pritzker School of Medicine, 950 East 59th Street, Chicago, Illinois, USA*

The differentiation of insulin-secreting tumours of the pancreas from other hypoglycaemic states is often difficult and time-consuming. Calcium infusion has been used in the diagnosis of gastrinomas, medullary carcinomas of the thyroid and carcinoid syndromes. The purpose of this paper is to report that this infusion is also useful in the preoperative diagnosis of insulinomas.

Thirteen patients with hypoglycaemia were evaluated by standard techniques—prolonged fasting, i.v. tolbutamide and oral glucose tolerance tests. In addition, each of these patients and 5 normoglycaemic volunteers received an infusion of calcium gluconate, 10 mg Ca^{++}/kg in saline over a 2-hour period. Peripheral blood which was drawn before and during these infusions was analysed for serum glucose, immunoreactive insulin and calcium concentrations. Eight of the hypoglycaemic patients were found at operation to have benign or malignant islet cell tumours of the pancreas; one child had islet cell hyperplasia and 4 patients were diagnosed as having reactive hypoglycaemia and were not operated upon.

In each of 8 patients with a confirmed islet-cell tumour, blood glucose values decreased within 60–90 min of the start of calcium infusion, necessitating the discontinuation of the infusion because of hypoglycaemic symptoms in most patients. Serum insulin values became clearly elevated above basal values in 6 of 8 patients. The serum glucose to insulin ratio decreased on all 8 patients. Postoperatively, calcium infusion was repeated in 5 patients in whom insulinomas had been removed. At this time no change in serum glucose or insulin levels occurred.

In contrast to the above individuals, in one patient with proved islet cell hyperplasia, in 4 patients with reactive hypoglycaemia and 5 in normoglycaemic volunteers, calcium infusion resulted in no changes in circulating glucose or insulin.

It is concluded that calcium infusion is a safe, rapid and effective provocative test which aids the preoperative diagnosis of benign or malignant insulin-secreting tumours of the pancreas.

10. The relationship between peptic ulcer localization and gastric acid secretion, gastric emptying and gastric secretion

R. BITTNER, H. G. BEGER, L. BITTNER, W. STEINERT and M. MEVES, *Department of Surgery, Klinikum Charlottenburg, Free University of Berlin, Spandauer Damm 130, D-1000 Berlin 19, West Germany*

It is generally accepted that there is a close relationship between the prepyloric gastric ulcer and the duodenal ulcer. However, the results of HSV in patients with a prepyloric ulcer are not encouraging. Therefore it is suggested that the underlying pathophysiologic mechanism is different from that producing duodenal ulcer.

Three groups with different localization of peptic ulcer were investigated:

Group I: Acute duodenal ulcer (DU) ($n = 36$; male 31, female 5; age: 37·5 yr (27–72)).
Group II: Prepyloric ulcer (PPU) ($n = 6$; male 4, female 2; age: 44 yr (32–57)).
Group III: High gastric ulcer (HGU) ($n = 10$; male 4, female 6; age: 60 yr (37–86)).

The following tests were performed: gastric acid output; gastric emptying and serum gastrin level before and after the ingestion of a semi-solid meal. For statistical analysis the Mann–Whitney U test was used.

BAO, MAO and PAO of the patients with DU are significantly higher than in the patients with a HGU ($P < 0{\cdot}001$). Patients with a PPU have a significantly higher PAO than the patients with a HGU ($P < 0{\cdot}05$) and show lower values compared to DU patients ($P < 0{\cdot}1$). The $T_{\frac{1}{2}}$ of the DU patients is 21 min shorter than the $T_{\frac{1}{2}}$ of the HGU patients ($P < 0{\cdot}1$). The PPU patients have again an intermediate position. In contrast to these results the gastrin levels of DU and HGU patients are nearly identical and both are much lower than in the PPU patients.

Patients with a prepyloric ulcer have a lower acid output and a longer $T_{\frac{1}{2}}$ than the patients with duodenal ulcer. However, most surprising is that the gastrin levels are nearly two-fold higher. These results suggest that the therapeutic approach in patients with a prepyloric ulcer may need reconsideration.

	Acid output (mmol/h)		
	BAO	MAO	PAO
DU ($n = 36$)	5·6 (0·6–18·5)	32·4 (14–52)	38 (15–67)
PPU ($n = 6$)	4·6 (0·5–7·2)	25·1 (7–39)	31 (8–45)
HGU ($n = 10$)	2·6 (0 14–8·8)	19·8 (3·7–24)	21 (6–31)

	Serum gastrin (ng/l)		Gastrin emptying (min)
	G_{basal}	G_{peak}	$T_{\frac{1}{2}}$
Control	42 (25–84)	110 (35–138)	59 (38–77)
DU ($n \doteq 36$)	52·5 (18–238)	110 (55–450)	46 (21–154)
PPU ($n = 6$)	82 (22–140)	201 (39–516)	50 (33–123)
HGU ($n = 10$)	57 (35–132)	98 (87–266)	67 (31–127)

Median levels and range.

11. Amino acids as possible mediators of the intestinal phase of gastric secretion

J. H. LANDOR, A. GOUGH, V. RAI and M. LIM, *Department of Surgery, CMDNJ-Rutgers Medical School, Piscataway, NJ, USA*

The recent demonstration that intravenous administration of a solution of L-amino acids (AA) evokes a gastric secretory response in dogs (Landor and Ipapo, 1977) and in man (Isenberg and Maxwell, 1978) has lent support to the idea that absorbed products of protein digestion account in part for the intestinal phase of gastric secretion In order to evaluate this possibility we measured Heidenhain pouch secretion and plasma amino nitrogen (PAN) in dogs subjected to 2-hour infusions of AA given via different routes. In 6 dogs, 4 infusions into the portal venous system and 4 infusions into the jejunum were carried out; in 4 dogs with portacaval transposition, 4 infusions into peripheral veins and 4 infusions into the jejunum were done.

In the first group of dogs, in which AA were infused into, or absorbed into, the portal circulation, mean secretion was 4·6 per cent of the maximal histamine response (MHR) after portal infusion and 3·9 per cent MHR after intrajejunal infusion ($P>0\ 6$); comparable figures for PAN were 5·3 mg/100 ml and 5·8 mg/100 ml ($P>0{\cdot}6$). Among the dogs in which AA was infused into, or absorbed into, the peripheral circulation, mean secretion was 21 per cent MHR after i.v. AA and 19·4 per cent MHR after intrajejunal AA ($P>0{\cdot}36$); PAN was 7·5 mg/100 ml and 6·4 mg/100 ml respectively ($P>0{\cdot}13$). Thus, in these two differing circumstances, gastric secretion and PAN were comparably elevated by infusion of AA into the venous circulation or into the gut. The data support the contention that absorbed amino acids account for a substantial portion, if not all, of the intestinal phase of secretion.

LANDOR J. H. and IPAPO V. S. (1977) Gastric secretory effect of amino acids given enterally and parenterally in dogs. *Gastroenterology* **73**, 781–784.

12. Endogenous immunosuppression, plasma inhibitors and the outcome of renal transplantation

D. N. H. HAMILTON, VIRGINIA JACKSON, MARY WATSON and J. D. BRIGGS, *Renal Unit and University Department of Surgery, Western Infirmary, Glasgow*

Evidence now suggests that the residual cell-mediated immunity of the regular dialysis treatment (RDT) patients, as tested with dinitrochlorobenzene (DNCB), plays a role in the outcome of renal transplantation (Rolley et al., 1977; Diamondopoulos et al., 1978). In this study the results of quantitative DNCB testing and the outcome of transplantation in 47 first cadaver kidney transplants is reported and the analysis of serum factors blocking lymphocyte response to the mitogens PHA, PWM and Con A. Mitogen responses are given as the stimulation index in control plasma or in the patients' own (autologous) plasma.

	DNCB score 0–3	 3+	*P*
6 m graft Survival	71%	17%	
Control plasma			
PHA	67±16	148±54	n.s.
PWM	32±10	86±26	$P<0{\cdot}05$
Con A	19±7·5	43±10·1	$P<0{\cdot}05$
Autologous plasma			
PHA	61±21	128±65	n.s.
PWM	30±12	92±33	n.s.
Con A	13·7±5·7	43±11·9	$P<0{\cdot}05$

These results show that the good graft outcome in RDT patients with a low DNCB response is associated with a depression of mitogen response of the lymphocytes from the low DNCB responders. This depression was seen in control plasma; autologous plasma gave an additional small depression of the response. It is concluded that the failure of RDT patients to respond to DNCB is associated with depressed lymphocyte function, and serum factors play a lesser role.

13. Transplantation tolerance following total lymphoid irradiation [TLI] and allogeneic bone marrow (BM) injection in primates

J. A. MYBURGH, J. A. SMIT, S. BROWDE and R. HILL, *Transplantation Research Unit, Department of Surgery, University of the Witwatersrand Medical School, Johannesburg, South Africa*

Tolerance to allogeneic skin and heart grafts and stable chimerism can be established in rodents by TLI and allogeneic BM injection (Slavin et al., 1978). The application of this concept has been studied in liver allotransplantation in two groups of outbred Chacma baboons. Group 1 (6 baboons) received 800 rad to the thorax and abdomen in two fractions 24 h apart, with shielding of the lungs and iliac crests. Five baboons received 6 3–40·4 × 10^7 nucleated BM cells per kg after the second fraction of irradiation, followed immediately by an orthotopic liver allograft from the BM donor. Four animals died 7, 8, 9 and 9 days after transplantation from massive intraperitoneal haemorrhage. All were profoundly thrombocytopenic on day 6. Histology of the liver at autopsy showed minimal or no evidence of cellular rejection. One baboon survived for 47 days (median survival of untreated controls, 19 days). The sixth animal received donor BM and a liver allograft 79 days after TLI, and is alive 32 days after transplantation. Group 2 (4 baboons) received eight 200 rad fractions to the torso without lung shielding in 15 days, followed immediately by allogeneic donor BM (4·4–13·6 × 10^7/kg). Orthotopic liver transplantation from the BM donors was carried out 15–23 days later. All animals are alive 46–54 days after transplantation. Two baboons have had normal serum bilirubin values throughout, and may be fully tolerant. BM chimerism has been documented in 2 animals, without any clinical evidence of graft versus host disease. Two baboons have developed anti-donor B cell antibodies after transplantation. Cell mediated lympholysis has been persistently negative in all animals and their T cells have remained unresponsive to phytohaemagglutinin.

SLAVIN S., REITZ B., BIEBER C. P. et al. (1978) Transplantation tolerance in adult rats using total lymphoid irradiation. *J. Exp. Med.* **147**, 700–707.

14. Ia (DRw) antigen expression on human kidney and other tissues

KERYN A. WILLIAMS, D. N. J. HART, J. W. FABRE and P. J. MORRIS, *Nuffield Department of Surgery, University of Oxford, Radcliffe Infirmary, Oxford*

It has been shown recently that renal transplantation can be performed successfully in the presence of donor-specific sensitization as shown by a positive crossmatch (previously considered an absolute contraindication to transplantation) where the antibody in the recipient is directed against B lymphocyte antigens. These antibodies against donor B lymphocytes have been considered to be directed in part against HLA-DRw antigens, analogous to the Ia antigens in the mouse. These antigens were thought to have a limited tissue distribution, being expressed on B lymphocytes and macrophages, but not on renal tissue in particular. This has been considered an explanation for the success of a renal transplant performed in the presence of this type of positive crossmatch. Recent animal studies, however, have demonstrated the presence of Ia antigens in substantial amounts on a wider range of tissues, including kidney in both rat and guinea-pig.

Two monoclonal antibodies against HLA-DRw and HLA-ABC were produced by hybridomas formed from a mouse myeloma/mouse spleen cell fusion, following hyperimmunization of the spleen cell donors with membranes from a lymphoblastoid B cell line and tonsil leucocytes, respectively. These antibodies were absorbed quantitatively with ten different human tissues and assayed in an indirect binding radioimmunoassay. Three separate normal kidney homogenates absorbed the anti-Ia activity as strongly as spleen (which carries a large amount of Ia antigen because of its large population of B lymphocytes). Liver and heart were tenfold and thirtyfold less effective by absorption. Ia was also detected in quantity on chronic lymphatic leukaemic cells, in marginal mounts on brain, on a small population of thymocytes and not at all on erythrocytes, platelets or reticulocytes. The distribution of HLA-ABC was widespread, as expected.

We conclude that human Ia antigens are expressed in different amounts on the commonly transplanted organs, kidney, liver and heart. Previous hypotheses of graft rejection and its suppression based on the absence of Ia antigens on human kidney are no longer acceptable.

15. Survival rates of immediately vascularized skin allografts

L. J. PERLOFF and C. F. BARKER, *Department of Surgery, University of Pennsylvania, Philadelphia, USA*

A model for immediate vascularization of skin was devised to examine one explanation of the differential survival rates of freely grafted skin and organs, i.e. the increased vulnerability of skin to early ischaemic necrosis. Fischer (F) rat skin was transplanted beneath the kidney capsule of tolerant Lewis (L) recipients. This skin healed in normally and, after 30 days, the skin-kidney grafts were excised and immediately revascularized by microvascular techniques in normal L recipients (syngeneic to the kidney portion of the graft, allogeneic to the skin). For 5 days after transplantation of the composite graft, the skin appeared normal in 11 recipients. From 6 to 11 days, in 6 rats, an active inflammatory response developed at the skin–kidney interface. In 10 rats, after 12–21 days, rejection of the skin was complete. The renal portion of all composite grafts appeared normal and all recipients of composite grafts rejected orthotopic F skin in an accelerated manner (median survival times: 8·2 *v.* 11·5 days in F→L controls), demonstrating that the skin on the composite graft had retained its antigenicity. These results demonstrate that immediately vascularized skin allografts will still be rejected within 2 weeks compared to survivals of up to 48 weeks for renal allografts across the same histocompatibility barrier. Anatomical factors are not sufficient to account for the differences in survival times between skin and solid organs.

16. Studies of the action of cyclosporin A on rabbit renal allografts

D. C. DUNN and D. J. G. WHITE, *Addenbrooke's Hospital, Hills Road, Cambridge*

We have used Cyclosporin A (Cy A) in over 80 renal allografted nephrectomized rabbits and shown that grafts can remain in excellent condition for as long as 257 days on continuous treatment. Early rejection has not followed cessation of treatment after 28 days or 18 days. It has been suggested that such courses of Cy A treatment, given with an antigenic challenge, can result in permanent specific allograft acceptance, by destroying the clones of lymphocytes reacting to that antigen. However, in our experience this post treatment 'tolerance' is not in fact wholly specific as we have shown that second kidneys taken from a third party donor can be accepted during this period.

We now present the results of giving Cy A (25 mg kg^{-1} d^{-1} i.m.) for (*a*) 14 days only after grafting and (*b*) for 14 days stopping 7 days before grafting.

Results: (*a*) Eleven rabbits treated after grafting have a mean survival so far of over 40 days (untreated: mean = 11 days, $P<0\cdot001$). Five are still alive and 3 have so far accepted their allografts for 3 months. Two delayed rejections have occurred at 44 and 54 days.

(*b*) Five rabbits grafted 1 week after treatment ceased have a mean survival of over 26 days so far ($P<0\cdot01$). Three are still alive at up to 45 days. Two died of tubular necrosis at 5 and 13 days with no significant rejection on histology.

These results show that 14 days' Cy A therapy is sufficient to induce the long term allograft acceptance state. However, we have seen delayed rejection in this group, even when therapy was continued as long as 56 days. No such rejection has yet been seen in rabbits given continuous therapy.

The unexpected and unique finding that prior treatment alone is immunosuppressive indicates that Cy A persists in the recipient and this must be taken into account in understanding post-Cy A 'tolerance'.

Overall our results favour a prolonged and not wholly specific effect of Cy A treatment which may wear off very slowly. They do not lend support to a theory of permanent specific clonal deletion by the drug.

17. Transfusions of whole blood, leucocytes and erythrocytes and renal allograft survival in DLA-typed beagles

H. OBERTOP, A. B. BIJNEN, H. M. VRIESENDORP and D. L. WESTBROEK, *Laboratory for Experimental Surgery, Erasmus University, Rotterdam, The Netherlands*

Blood transfusions have a protective effect on a subsequent kidney allograft in man. However, the optimal transfusion policy of patients with an end-stage renal failure is not known. Besides the beneficial effects, blood transfusions carry the risk of inducing lymphocytotoxic allograft antibodies that can exclude potential recipients from kidney transplantation or have a deleterious effect on the graft. Experiments have been carried out to study the effect of blood transfusions on renal allograft survival in some 80 DLA-typed beagles. Pretreatment with kidney blood donor (i.v. or s.c.) did not prolong graft survival but led to positive cross-match tests and accelerated graft rejection in the pretreated dogs. Transfusions with pooled third party blood before transplantation induced a broad spectrum of antibodies and did not give rise to graft protection although no accelerated graft rejection was seen. Immune response against a random panel was not genetically determined and did not correlate with graft rejection. Transfusions of (non-pooled) third party blood and postoperative immunosuppression led to absence of graft rejection in 6 out of 10 transfused beagles, whereas of 9 non-transfused control littermates only one was a long term survivor. To determine which fragment of the whole blood was responsible for the protection of the future allograft, 12 DLA-typed beagles were transfused with three erythrocyte suspensions (ERY) of different non-related donors and 12 littermates were transfused with three leucocyte suspensions (LEU) of the same donors. Two weeks after the last transfusions kidneys from non-related mongrel donors were grafted to both erythrocyte and leucocyte pretreated beagle littermate recipients. Immunosuppressive treatment was given postoperatively (Imuran 2 mg/kg, prednisolone 1 mg/kg i.v.). Immunoresponsiveness was measured before transplantation. The survival times are given below and can be compared with similar data of whole blood (WB) and non-tranfused (NTR) dogs.

ERY: 5+, 7+, 9, 16+, 24, 47, 51, >60+, >60+.
LEU: 4+, 6+, 8, 12, 32, >60, >60, >60, >60.
WB: 21, 26, 51, >60, >60, >60, >60, >60, >60.
NTR: 11, 15, 16, 19, 20, 29, 30, 48, >60.

+ = Positive cross-match before transplantation between kidney donor and recipient.

It is concluded that (*a*) specific immune response could not be measured in the beagle recipients; (*b*) protective effect on renal allograft pretreatment with third party blood transfusions was only apparent when immunosuppression was given postoperatively; (3) the protective effect could not solely be contributed to the erythrocytes or leucocytes.

18. Postoperative pulmonary dysfunction: the role of intravascular platelet aggregates

C. N. MCCOLLUM and L. T. CAMPBELL, *St James' University Hospital, Leeds*

Postoperative hypoxia, a common clinical problem, is widely thought to result primarily from respiratory suppression due to anaesthesia and wound pain. However, in trauma patients attention has recently focused upon the possible role of intravascular platelet aggregates (IPA) in pulmonary damage following shock (Moseley and Doty, 1970). IPA may now be measured reproducibly by a modified screen filter technique and can be demonstrated in patients after major surgery (McCollum, 1978). In this study we investigated the relationship between IPA levels and postoperative dysfunction.

In 20 patients, IPA levels were measured by screen filtration of femoral vein blood 30 min and 3 h following surgery. Pulmonary function (arterial Po_2, physiological dead space and alveolar/arterial Po_2 gradient) was estimated preoperatively and on days 1 and 7 postoperatively. A significant relationship was noted between these IPA levels and subsequent measurement of pulmonary function. In patients with elevated IPA levels the mean fall in arterial Po_2 was greater at 7 days (1·8 kPa, 13·5 mmHg) than in patients with normal IPA levels (0·7 kPa, 5·4 mmHg) ($P<0·05$). This was explained by a marked increase in alveolar/arterial Po_2 gradient in these patients (2·2 kPa, 16·5 mmHg *v.* 0·5 kPa, 3.6 mmHg) ($P<0·01$). The postoperative fall in platelet count was the only other parameter which was related to pulmonary dysfunction on day 7.

These results indicate that elevated IPA levels immediately after surgery predict pulmonary dysfunction 1 week later. Therapeutic manoeuvres to prevent IPA may conceivably reduce postoperative hypoxia.

19. Effects of burn injury and sepsis on visceral blood flow

C. W. GOODWIN, L. H. AULICK, R. A. BECKER, J. P. LIMBACHER and D. W. WILMORE, *United States Army Institute of Surgical Research, Brooke Army Medical Center, Fort Sam Houston, Texas, USA*

Most of the increase in cardiac output in thermally injured patients is directed to the burn wound, but flow to visceral tissues remains poorly defined. In this study, visceral circulation and oxygen uptake were determined by measuring splanchnic blood flow (ICG extraction), renal blood flow (PAH clearance), cardiac index (dye dilution), total body oxygen consumption and regional oxygen extraction (A-Vo_2 by selective venous catheterization) in 9 uninjured controls and in 19 non-infected burn patients (mean burn size 47 per cent TBS) studied 7–21 days after injury. To assess the added impact of sepsis, 10 normotensive, bacteraemic burn patients (59·5 per cent TBS) were also studied. Results are expressed as mean±s.e. mean, flow in $1\ \text{min}^{-1}\ \text{m}^{-2}$, and A-Vo_2 in ml/100 ml blood.

	Total body		Splanchnic	
	Flow*	A-Vo_2	Flow	A-Vo_2
Normals	3·43	3·73	0 74†	4·5†
	±0 22	±0·12		
Non-infected	7·80	3·33	1·38	4·80
	±0·42	±0·58	±0·10	±0·29
Bacteraemic**	8·52	2·86	1·78	3·94
	±0·35	±0·17	±0·19	±0·52

	Renal	
	Flow	A-Vo_2
Normals	0·55	1·70†
	±0·04	
Non-infected	0·81	2·10
	±0·08	±0·12
Bacteraemic**	1·97‡	0·98
	±0·38	±0·19

* Cardiac index; † From literature; ‡ $n=3$, assumed PAH extraction ratio = 0·46†.

** Only significant differences between patient groups were in renal values, $P<0·001$.

Both splanchnic and renal flow are increased as a direct consequence of injury. The elevated visceral blood flow in non-septic patients appears appropriate for heightened metabolic demands, since regional A-Vo_2 differences remain essentially normal. The added insult of sepsis did not significantly alter total body and splanchnic blood flow but appeared to increase renal perfusion in excess of aerobic requirements.

20. Role of the carotid sinus reflex as a possible mechanism of the effect of intra-aortic balloon pumping for the treatment of shock

M. HORI and H. MAETA, *Department of Surgery, Institute of Clinical Medicine, The University of Tsukuba, Tsukuba Ideopolis, Ibaraki 300-31, Japan*

Intra-aortic balloon pumping (IABP) is now widely used as an effective adjunct to medical and surgical therapy of either cardiogenic shock secondary to acute myocardial infarction or post-surgical acute heart failure, or the inability to wean from cardiopulmonary bypass.

The mechanisms of the effect of IABP have been explained by the following: (*a*) augmentation of the coronary artery blood flow during ventricular diastole; (*b*) unloading of left ventricular afterload during systole resulting in a decrease in the left ventricular end-diastolic pressure due to the mechanical balloon counterpulsation in the descending thoracic aorta.

In this report the predictive value of the carotid sinus baroreceptor response to the diastolic IABP is described as another possible mechanism to explain the improvement of cardiocirculatory dynamics following the IABP.

In the mongrel dog, firing impulses were introduced and recorded from the carotid sinus nerve during IABP. ECG, carotid pressure, flow and venous pressure were monitored.

The burst of impulses was initiated by the diastolic rise in the carotid pressure during IABP, less impulses being observed during systole and even less during diastole.

During the cardiac cycle with IABP the average activity of the carotid sinus nerve was 70 000 µV/ms whereas during the cardiac cycle without IABP the average activity was 52 000 µV/ms.

With increase in blood pressure in the carotid, the frequency of firing of the sinus nerve is enhanced. An increase in firing, as occurred in the phase of diastole with IABP, might act to inhibit the vasoconstrictor centre by a reflex mechanism resulting in peripheral vasodilatation and lowering the systemic vascular resistance in shock state.

The role of the carotid sinus reflex is a possible mechanism for the effect of IABP.

21. The hepatic handling of bromsulphthalein (BSP) following graded haemorrhage

J. HAM and MARGARET ROSE, *School of Surgery, The University of New South Wales, Sydney, Australia*

Hepatic decompensation is well recognized following major surgery or trauma. An important contributing factor is blood loss, but it is not known whether the magnitude of the change in hepatic function correlates with the severity of the blood loss. In this study, the hepatic handling of BSP has been measured in pigs following mild, moderate and severe haemorrhage (10 per cent, 20 per cent and 30 per cent of calculated blood volume).

The experiments were performed in anaesthetized animals 3 days after the placement of sampling catheters in the hepatic inflow and outflow vessels, and the construction of an external bile shunt. BSP was infused at a rate of 0·59 $\mu\text{mol kg}^{-1}\ \text{min}^{-1}$ and bile flow, BSP concentration in serum and bile, and BSP conjugates in bile were measured for 6 h after the bleed.

There was a significant reduction in the proportion of BSP conjugates in bile, and there was a significant positive correlation between the degree of this reduction and the degree of blood loss.

The mechanism of this reduced biliary excretion of BSP conjugates may be the result of impairment of BSP conjugation or inhibition of biliary excretion of conjugates or both.

22. Studies on the plasma kallikrein-kinin system during experimentally induced endotoxaemia in dogs and septicaemia in man

A. O. AASEN, M. J. GALLIMORE, N. SMITH ERICHSEN, K. N. LYNGAAS, M. LARSBRAATEN and E. AMUNDSEN, *Institute for Surgical Research, Rikshospitalet and Department of Anaesthesia, Akershus Central Hospital, Oslo, Norway*

Various studies over the past decade have suggested that the plasma kallikrein-kinin system becomes activated during experimentally induced endotoxaemia in animals and septicaemia in man. Using a large number of tests including newly developed assays with chromogenic peptide substrates, we have studied various components of the plasma kallikrein-kinin system in endotoxaemia in a dog model and in plasma samples from normal subjects and patients with septicaemia. Endotoxin shock was induced in Labrador retriever dogs by infusing a lethal dose (6 mg/kg) of *E. coli* endotoxin over a 3 hour period. Plasma levels of prekallikrein (PKK), kallikrein (KK) and kallikrein inhibitors (KKI) were monitored during and after the infusion, using a chromogenic peptide substrate for plasma KK (Chromozyme-PK, Pentapharm, Basle, Switzerland). High molecular weight kininogen (HMwK) levels were determined by incubating plasma samples with purified human plasma kallikrein and determining the bradykinin liberated on the isolated rat uterus. Considerable reductions in plasma levels of PKK and HMwK were seen in the collapse samples and free KK and KK bound to α_2-macroglobulin (α_2M) were detected. Functional KK inhibition (KKI) was also reduced.

Levels of Hageman factor (HF), KK, PKK, HMwK, KKI and concentrations of C^1-esterase inhibitor (CIINH, the major protease inhibitor in the plasma KK-kinin system), α_2M and α_1-antitrypsin (α_1AT) were determined in plasma samples from normal individuals and patients with septicaemia. Considerably lower levels of HF, PKK and HMwK and lower levels of KKI and α_2M were found in patients with septicaemia of fatal outcome. Spontaneous KK activity was higher and markedly increased concentrations of CIINH and α_1AT were also found. Our results emphasize that the plasma KK-kinin system becomes activated during experimentally induced endotoxaemia in dogs and septicaemia in man and suggest that the resulting release of bradykinin contributes to the development of shock in this state. During both endotoxaemia and septicaemia, consumption of components of the system (HF, PKK and HMwK) occurs, plasma KK activity can be detected in the plasma and functional kallikrein inhibition is markedly reduced. Because mean plasma levels of PKK, HMwK and CIINH were higher in 3 patients with septicaemia who subsequently recovered, and functional KKI was normal, it is probable that functional kallikrein inhibition of active proteases in septicaemia contributes to survival.

23. The metabolism of biogenic amines during septic shock

M. KERSTEIN, S. GOULD, G. MOSS, C. RICE, L. SEHGAL, P. MOSELEY, J. KOHLER, A. ROSEN, H. LEVINE, B. DULSKI and R. DEWOSKIN, *Department of Surgery, Michael Reese Hospital and Medical Center University of Chicago, Chicago, Illinois, USA*

It is the purpose of this investigation to determine the effect of *E. coli* induced shock on the capacity of the lung to extract two biogenic amines, adrenaline (A) and 5-hydroxytryptamine (5-HT). Four adult male baboons were anaesthetized, intubated and ventilated. Sepsis was induced by a continuous 4-h intravenous infusion of live *E. coli*. Blood gases and central haemodynamic pressures were serially recorded. Simultaneous indicator dilution curves were generated using ^{14}C-labelled 5-HT and ^{3}H-labelled A. The labels were injected into a central vein and collected from an aortic catheter.

The increased recovery of 5-HT following septic shock may be explained by (*a*) increased arteriovenous pulmonary shunting, (*b*) capillary endothelial damage or (*c*) interstitial pulmonary oedema inhibiting pulmonary metabolism.

It is concluded that septic shock reduces pulmonary extraction of 5-HT in the baboon. These data suggest that pulmonary endothelial metabolism is significantly altered during acute sepsis.

Table I: RECOVERY OF A AND 5-HT

	Percent recovery		
	Before sepsis	After sepsis	
A	100%	100%	n.s.
5-HT	32·8±3·6%	42·5±4·9%	$P<0·05$

Table II: MEAN ARTERIAL AND PULMONARY WEDGE PRESSURE

	Before sepsis	After sepsis	
MAP	121·3±9·6 mmHg	58·8±15·4 mmHg	$P<0·05$
PAWP	13·0±1·5 mmHg	21·3±4·9 mmHg	n.s.
Qs/Qt	0·07±0·05	0·33±0·09	$P<0·05$

All results: mean±s.e. mean.

24. A single fibre electromyographic study of the external anal sphincter in normal subjects, rectal prolapse and in anorectal incontinence

M. E. NEILL, M. SWASH and A. G. PARKS, *St Mark's Hospital, London*

In the past, investigation of patients with anorectal incontinence has relied on anal pressure studies, supported by electromyography and, more recently, by study of the anal reflex (Henry and Swash, 1978). Parks et al. (1977) reported histological abnormalities in the anal musculature, and suggested that the innervation of the external sphincter (EAS) and puborectalis muscles was damaged in these patients.

In order to study the functional disorder in the EAS, we have utilized the single fibre technique devised by Stålberg and Ekstedt (1973). This technique gives a quantitative measure of the mean number of muscle fibres supplied by a motor unit within the uptake radius of the electrode tip: the fibre density (FD). In 13 normal subjects aged 20–80 years the mean FD was 1·5 (s.d. 0·2). In 14 patients with idiopathic anorectal incontinence with delayed anal reflex latency, the mean FD in the EAS was 2·14 (s.d. 0·28) ($P\pm0·001$). In 10 patients with rectal prolapse without incontinence the mean FD was 1·9 (s.d. 0·27) ($P<0·01$).

These results suggest that the pattern of innervation of the EAS has become reorganized in idiopathic anorectal incontinence and is consistent with histological abnormalities described.

Single fibre electromyography may be useful in the assessment of patients with anorectal disorders since an increase in FD may be a predictor of future incontinence.

25. Intestinal motility and acute alcohol ingestion: electromyographic studies in dogs

F. ANGEL, P. SAVA, A. JIMENEZ GARCIA, F. CRENNER, P. BOUCHET and J. F. GRENIER, *Inserm Unite 61, 3 Avenue Molière, 67200 Strasbourg, Hautepierre, France*

The fasting state in dogs is characterized by a cyclic phenomenon, the myoelectric complex (MC). The most characteristic phase of the MC is phase III that recurs about every 90 min. The aim of this work is to study the effects of acute alcohol ingestion on MC recurrence.

Two groups of 5 dogs are prepared with a duodenal cannula allowing direct intraduodenal administration (IDA) of alcohol. Electrodes implanted on jejunal serosa allow chronic recordings of intestinal myoelectrical activity. In each dog of group one the effects of alcohol IDA are studied with solutions of three concentrations (4 per cent, 6 per cent and 8 per cent v/v). In each dog of group two, IDA of the 4 per cent alcohol solution is tested and blood alcohol concentration (BAC) is studied every 20 min after the beginning of IDA. In each experiment the solution administered (volume of 300 ml) takes 30 min to perfuse.

In group one, taking each dog as its own reference, a significant recurrence delay in phase III of 30±15 min, 60±15 min and 100±25 min is observed after IDA of solutions respectively of 4 per cent, 6 per cent and 8 per cent alcohol. In group two, the curves of BAC versus time show a phase of fast increasing BAC followed by a phase of slow decreasing BAC. The peak value of the curve occurring at 85±15 min after IDA beginning in all dogs is significantly different in each dog.

The recurrence of phase III is observed 120±15 min after beginning of IDA when BAC decreases.

We conclude that: (*a*) alcohol at a concentration over 4 per cent induces a delay of MC recurrence related to the dose administered; (*b*) for the same alcohol concentration reappearance of phase III of the MC is independent of maximal BAC and occurs after maximal alcohol absorption rate is reached. This suggests that alcohol acts very rapidly on intestinal motility.

26. Evidence for the flutter valve mechanism of the lower oesophageal high pressure zone (HPZ)

J. CLARK and A. CUSCHIERI, *Department of Surgery, Ninewells Hospital and Medical School, Dundee*

As the HPZ pressure does not adequately reflect competence at the cardio-oesophageal junction (Clark et al., 1976), a study was undertaken to assess the force exerted by the HPZ and its intra-abdominal segment in relation to reflux control. Simultaneous manometry, HPZ length and oesophageal pH were recorded in 189 patients at rest and during raised intra-abdominal pressure produced by 50·0 mmHg abdominal cuff compression after the instillation of 300 ml 0·1 HCl in the stomach. The force in Newtons × 10^{-2} was calculated for 1·0 cm strips of both the entire length of the HPZ and its intra-abdominal segment (IAS) as follows: force = length (cm) × breadth (cm) × pressure (mmHg) × 1·33.

During abdominal compression, 102 patients refluxed as shown by a fall in the oesophageal pH to below 4 0.

The results obtained are shown in the following table:

	Force (N × 10^{-2} [$\bar{x}$, s.e. mean]) HPZ	
	Rest	Compression
Refluxers (n = 102)	63·2±4·0	*38·1±2·8
Non-refluxers (n = 87)	97·2±5·1	*63·3±3·5

	Force (N × 10^{-2} [$\bar{x}$, s.e. mean]) IAS	
	Rest	Compression
Refluxers (n = 102)	32·4±2·9	*16·8±1 7
Non-refluxers (n = 87)	59·1±3·5	*34·3±2·7

$P < 0·001$ rank sum.

The force ratio IAS/HPZ fell below 0·5 (0·44) only in the reflux group during abdominal compression indicating that increased intra-abdominal pressure in these patients causes a reversal of the force distribution of the HPZ on either side of the diaphragm.

It is concluded that the resting HPZ force, like the resting HPZ pressure, does not determine competence at the cardio-oesophageal junction which appears to depend on the reserve of force (and pressure) which ensures the persistence of a threshold barrier against reflux whenever intra-abdominal pressure is raised, and maintains a force differential along the HPZ in favour of the intra-abdominal segment. These findings suggest that the HPZ behaves like a flutter valve and argues against it being a physiological sphincter.

27. The effect of experimental chemical uraemia on serum gastrin levels in dogs

S. H. DOUGHERTY, S. B. VOGEL, S. NOMIYAMA and M. M. EISENBERG, *Department of Surgery, University of Minnesota, Minneapolis, USA*

The hypergastrinaemia of renal failure is now well recognized (Falcao et al., 1975). Whether uraemia *per se*—in addition to the loss of functioning renal parenchyma—can produce hypergastrinaemia, however, is unclear (Davidson et al., 1974). This study was undertaken to clarify this question, as well as to clarify the effect of acute uraemia on BAO.

Five dogs underwent studies of BAO and arterial pH before and after bilateral nephrectomy. Acute uraemia was produced in two other groups of dogs by bilateral ureteral ligation or bilateral ureterovena caval diversion. The latter procedure produces the chemical changes of uraemia while leaving the kidneys structurally intact. Control and postoperative values of BUN, creatinine and serum gastrin were determined for all three groups.

The nephrectomized dogs showed a twentyfold increase in BAO during the postoperative period which was significantly greater than the average control value ($P < 0 001$). This acid hypersecretion was not associated with arterial acidosis. Marked hypergastrinaemia—to average levels as high as 422 ng/l—tended to parallel massive uraemia in all three experimental groups. Serum gastrin levels did not correlate with BAO.

Uraemia *per se*—not just the loss of renal parenchymal mass—plays a role in the genesis of uraemic hypergastrinaemia in dogs. In addition, factors other than—or in addition to—serum gastrin levels may be responsible for the gastric secretory response in uraemia.

28. The importance of blood flow in the ability of gastric mucosa to maintain its intramural pH

L. Y. CHEUNG, *Department of Surgery, Washington University School of Medicine, St Louis, USA*

In spite of the presence of intraluminal bile salts and acid and its consequent back diffusion of H+, acute gastric ulcers do not occur unless ischaemia is also present. This observation suggests that, in the presence of normal mucosal blood flow (MBF), gastric mucosa is able to dispose of the influxing H+ and to prevent acidification and ulceration of the mucosa.

	Before ischaemia	
	Control	Test
MBF (ml min^{-1} g^{-1})	1·4±0·3	1·9±0·4
H^+ flux (μmol/min)	1·2±0·5	−6·1±0·8*
Intramural pH	7·2±0·1	7·2±0·2
Ulceration (%)	0/14 (0%)	0/14 (0%)

	During ischaemia	
	Control	Test
MBF (ml min^{-1} g^{-1})	0·2±0·1	0·3±0·2
H^+ flux (μmol/min)	1·8±0·6	−2·6±0·3*
Intramural pH	7·2±0·1	6·9±0·1*
Ulceration (%)	0/14 (0%)	13/14 (93%)*

Mean ± s.e. mean. *$P < 0·01$ when compared with control.

To evaluate this hypothesis, we determined the intramural pH of gastric mucosa using the microelectrode technique (Kivilaakso et al., 1978) in the presence of (*a*) back diffusion of H^+ and normal MBF, (*b*) back diffusion of H^+ and ischaemia and (*c*) ischaemia alone without back diffusion of H^+. In 19 dogs a portion of fundic stomach with intact vascular pedicle was placed in a single (n = 10) or a double (n = 9) lumen chamber. The control mucosae were bathed with acid solution (70 mmol HCl+80 mmol NaCl). Sodium taurocholate (5 mmol) was added to acid solution of test mucosae. After a normotensive period of 60 min, all mucosae were subjected to ischaemia induced by withdrawal of blood of 2 per cent of body weight for another 60 min. MBF was measured by gamma-labelled microspheres.

These results support the hypotheses that (*a*) adequate MBF (before ischaemia) disposes of influxing H^+ and maintains normal intramural pH and morphologic integrity of the mucosa even in the presence of back diffusion of H^+ and (*b*) ischaemia results in acidification and severe ulceration of the gastric mucosa as a consequence of compromised ability to dispose of H^+.

29. Is osmotic control of gastric emptying still present after vagotomy?

M. J. GOUGH, C. S. HUMPHREY, C. S. MARSHALL and G. R. GILES, *University Department of Surgery, St James's University Hospital, Leeds*

Gastric emptying of liquid test meals is partly controlled by osmoreceptors situated in the duodenum. It has been reported that vagotomy abolishes this control (Hall and Read, 1970). In this study we have used the George technique to measure gastric emptying of 5 per cent and 10 per cent glucose test meals in 43 patients with duodenal ulcer, 17 patients with a recurrent ulcer and incomplete vagotomy and 35 patients who were symptomatic with an apparently complete vagotomy.

The results shown in the Table indicate that patients with a duodenal ulcer empty 10 per cent glucose meals significantly slower than 5 per cent glucose. It is also clear that regardless of the completeness of vagotomy the 10 per cent glucose test meal is emptied significantly slower than 5 per cent glucose in all postoperative patients, indicating a persistence of osmoregulatory control. Both postoperative groups of patients empty both types of test meal significantly faster than non-operated patients ($P<0{\cdot}01$).

Regrouping the postoperative patients irrespective of the completeness of vagotomy into 22 patients with a pyloroplasty and 30 patients with gastroenterostomy revealed that patients with a pyloroplasty did not retain significant differences in emptying of the two test meals whereas patients with a gastroenterostomy continued to empty the 10 per cent glucose significantly slower than the 5 per cent glucose.

These results suggest that osmoregulation of gastric emptying in the postoperative patient is not necessarily mediated by the vagus nerves and that the osmoreceptors are not confined to the duodenum.

Group	Indices	5% glucose	10% glucose
Duodenal ulcer	Starting index	5·0 min ± 2·4	19·3 min ± 2·5*

30. Multi-element analysis of the living body by neutron activation—a study of critically ill patients receiving intravenous nutrition (IVN)

G. L. HILL, R. F. G. J. KING, R. C. SMITH, C. B. OXBY, A. SHARAFI and L. BURKINSHAW, *University Departments of Surgery and Medical Physics, The General Infirmary, Leeds* (*see* pp. 868–872)

31. The postoperative insulin clearance of the human liver

E. KRAAS, H. G. BEGER, R. BITTNER and H. GOGLER, *Department of Surgery, Klinikum Charlottenburg, Free University of Berlin, Spandauer Damm 130, D-1000 Berlin 19, West Germany*

Animal experiments have shown that considerable amounts of insulin are removed by the liver. However, little information is available on hepatic insulin extraction in man.

In 10 non-diabetic surgical patients (5 M, 5 F) with normal liver function the hepatic insulin extraction rate was calculated by measuring simultaneously the insulin concentration in the portal and hepatic vein before, during and after i.v. glucose infusion ($1\ \mathrm{g\ kg\ BW}^{-1}\ 60\ \mathrm{min}^{-1}$). To demonstrate the enzymatic degradation of insulin by the human liver, insulin was incubated with the homogenates of 25 liver biopsies.

1. The hepatic insulin extraction rate ranges between 25 per cent (fasting state) and 60 per cent (after maximum glucose stimulation) of the portal venous insulin.
2. Up to a portal venous insulin concentration of about 400 U/l a linear correlation with the hepatic insulin extraction in man exists ($r = 0{\cdot}91$, $P<0{\cdot}0001$).
3. A soluble proteolytic hepatic enzyme which inactivates insulin was found in the $100\,000 \times g$ supernatant of human liver.
4. In fractionated liver homogenates, the $100\,000 \times g$ supernatant was found to be responsible for 88 per cent of the total hepatic insulin degrading activity in man. The V_{max} for insulin degradation was found to be $1{\cdot}75 \times 10^{-7}$ ($\simeq 68\ \mu g$ insulin/g liver).

The results demonstrate the important role of the human liver in the regulation of the postoperative insulin and glucose metabolism.

32. Influence of glucagon on plasma volume and osmolality during haemorrhagic shock

R. MENGUY and YANNA MASTERS, *Department of Surgery, University of Rochester, Genesee Hospital, 224 Alexander Street, Rochester, New York, USA*

Glucagon appears to improve some parameters of circulatory shock via a postulated positive inotropic effect. We have attempted to confirm this beneficial action and examine its mechanism. Rabbits, bled an amount equivalent to 25 per cent of their measured (^{131}I human serum albumin) blood volume were allowed to recover spontaneously during 90 min after which the shed blood was returned. Over the 90 min of hypovolaemic shock and the following 30 min of normovolaemic shock, we measured the following: arterial blood pressure (MABP), cardiac output (CO), superior mesenteric artery blood flow (SMABF), plasma volume (PV), arterial and venous haematocrits, glucose, lactate, Na, K and plasma osmolality. Thirty minutes after bleeding, the animals received a 30-min infusion of identical volumes of a solution of normal saline or of glucagon ($0{\cdot}04\ \mathrm{mg\ kg}^{-1}\ \mathrm{min}^{-1}$) or of xylose (0·6 mg/ml). Glucagon caused a marked improvement of CO and SMABF that lasted for at least 60 min after the infusion was over and that was mimicked by xylose. Animals receiving glucagon or xylose had a greater PV refill during shock than the controls. The greater repletion of PV was associated with and, we believe, caused by a greater rise in plasma osmolality. The latter was all accounted for in the case of the glucagon group by a marked enhancement of shock-induced hyperglycaemia. We suggest that glucagon increased the normal plasma refill during shock via a greater 'osmolar pull'. This, in conjunction with the lower total peripheral resistance brought about by a greater drop in haematocrit, suffices to explain the increases in CO and regional blood flow observed by others. According to this scheme, one would not expect glucagon to be effective in fasted animals or when prolonged shock has exhausted hepatic glycogen content. This may explain why some have not found glucagon to be beneficial.

33. Effect of epidural analgesia on postoperative sodium balance

N. MENZIES-GOW, J. P. S. COCHRANE and L. P. LE QUESNE, *Department of Surgical Studies, The Middlesex Hospital, London* (*see* pp. 864–867)

34. Isotope studies of substrate interaction in parenteral nutrition

D. CLARKE, MARY G. C. FINN, B. A. SUGDEN, A. J. W. SIM, V. R. YOUNG and F. D. MOORE, *Department of Surgery, Harvard Medical School at the Peter Bent Brigham Hospital, Boston; and Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge, USA*

Total body nitrogen turnover, protein synthesis and breakdown have been measured in normal men given intravenous nutrients, using 15 N glycine as a tracer (Picou and Taylor-Roberts, 1969).

Sim et al. (1979) showed that changeover from oral diet to isonitrogenous amino acid infusion, lowered protein synthesis from 2·4±0·3 s.d. to 1·0±0·13 g $\mathrm{kg^{-1}\,d^{-1}}$ and breakdown from 2·4±0·3 to 1·8±0·2. Addition of 'high dose' glucose (about 500 g) to the amino acid infusion (AA+HDG) increased protein synthesis to 1·6±0·13 g $\mathrm{kg^{-1}\,d^{-1}}$, breakdown remaining unchanged.

This paper reports extended studies of substrate interaction. Subjects were given amino acids and fat emulsion (AA+FE, $n=4$) and amino acids, fat emulsion with 'low dose' glucose (150 g) (AA+FE+LDG, $n=4$), on isocaloric, isonitrogenous regimens of 5 days' duration.

Nitrogen turnover was the same in both groups.

Protein synthesis (2·0±0·2 g $\mathrm{kg^{-1}\,d^{-1}}$) was higher with AA+FE+LDG than with AA+FE (1·6±0·2, $P<0·02$), or with AA+HDG (1·6±0·13, $P<0·02$). Protein breakdown was insignificantly different.

These data suggest that in normal fasting man a mixture of amino acids, low dose glucose and fat emulsion (tolerated by peripheral veins) will support protein synthesis as effectively as amino acids and high dose glucose given centrally.

35. Deleterious effect of glucagon therapy on the liver after hypotension

H. J. PROCTOR and J. J. WOOD, *Trauma Section and the Laboratory of Cellular Bioenergetics, Department of Surgery, University of North Carolina School of Medicine, Chapel Hill, North Carolina, USA*

Intravenous glucagon has been recommended to increase portal vein flow and oxygen delivery to the liver after periods of hypotension. It is also known that glucagon increases oxygen consumption of hepatocytes. The net effect of these antagonistic actions has not been well characterized.

In 20 dogs, hypotension was established by bleeding (mean arterial pressure 50 mmHg for 90 min followed by 35 mmHg for 30 min). Shed blood plus saline were used for resuscitation. Oxygen delivery [hepatic artery flow+portal vein flow × O_2 content] was measured using a standard technique. Liver biopsies were frozen in liquid nitrogen for determination of adenosine triphosphate (ATP), glucose and lactate. Randomly selected dogs received glucagon (6 μg/kg) as part of their regimen.

As anticipated, glucagon increased portal vein flow. Despite the increase in oxygen delivery and glucose availability after glucagon, a sustained significant ($P<0·05$) decrease in ATP was noted in the glucagon-treated animals. The equal and decreasing lactate concentration after resuscitation indicates that aerobic metabolism and tissue perfusion were adequate after resuscitation and that cytochrome function was intact. The authors postulate a direct, as yet unexplained, effect of glucagon on oxidative phosphorylation. Until this is clarified, there is little indication for glucagon therapy to augment liver perfusion after trauma.

	Baseline	End shock	30 min after resuscitation	240 min after resuscitation
No glucagon ($n=11$)				
ATP (μM/g)	2·38	0·72	1·65	1.91
Glucose (μM/g)	5·14	17·5	9·20	3·53
O_2 delivery (ml/min)	81·9	12·5	77·6	53·3
Lactate (μM/g)	1·54	12·04	13·38	6·51
Glucagon ($n=9$)				
ATP (μM/g)	2·42	0·47	0·94	0·86
Glucose (μM/g)	5·23	18·13	45·41	4·80
O_2 delivery (ml/min)	86·4	30·7	142·8	56·1
Lactate (μM/g)	2·75	13·98	18·72	11·63

36. The effect of smoking and diet on late failures after arterial reconstruction

R. M. GREENHALGH, SUSAN MILLS, P. V. COLE and G. W. TAYLOR, *Department of Surgery, Charing Cross Hospital, London*

Two hundred prospective consecutive patients were followed at 6-monthly intervals for 5 years. Their preoperative fasting triglyceride, cholesterol, lipoprotein, fibrinogen, uric acid and carboxyhaemoglobin levels were raised compared with normal controls. Of the 200 patients, 21 had a sympathectomy only and 179 had a reconstruction. Of the latter, 18 reconstructions failed within 3 months, 20 died, 19 were lost to follow-up, 25 reconstructions failed after 3 months and 97 operations were patent after 5 years. Lipid abnormalities were randomly allocated to be left untreated or controlled by diet.

Although dietary control was successful, fasting haematological data from 1296 patient visits has conclusively shown that triglyceride, cholesterol, lipoprotein, fibrinogen and uric acid levels are the same in the late reconstruction failure group as in the successful group. However, carboxyhaemoglobin levels are seen to be significantly higher in the late failure group.

We conclude that in these patients late graft failure is associated with continued heavy cigarette smoking and there is no evidence that successful dietary control of lipoprotein abnormalities has influenced the late outcome of arterial reconstructions.

37. Increased diastolic time: an independent factor for the beneficial effect of propranolol in patients undergoing coronary bypass surgery

H. BOUDOULAS, R. P. LEWIS, G. L. SNYDER, P. E. KARAYANNACOS and J. S. VASKO, *Ohio State University Hospitals, Columbus, Ohio, USA*

Continuation of propranolol through coronary bypass surgery (CBS) decreases the incidence of subendocardial infarction and postoperative supraventricular tachycardia (Boudoulas et al., 1978). Since subendocardial flow and flow distal to a significant coronary obstruction occurs almost entirely in diastole (Brown et al., 1974) an increase in diastolic time (DT) due to propranolol may increase subendocardial flow. DT, calculated as the cycle length (RR) minus electromechanical systole (QS_2), has a non-linear relationship to heart rate (HR) increasing rapidly as rates fall below 75 (Boudoulas et al., 1978). DT, 15 h before and 2 weeks after CBS, was compared in 50 patients who underwent CBS not on propranolol (group 1) and 30 patients maintained on propranolol through CBS (mean daily dose 155±11 mg preop. and 68±9 mg postop.) (group 2).

	Before CBS		After CBS	
	Group 1	Group 2	Group 1	Group 2
HR (beats/min)	81±2	62·8±2*	95±2	73±2*
DT (ms/beat)	396±16	575±25*	339±12	426±12*

Values are ±s.e. mean.

Difference between the groups $P<0·05$.

Since sinus tachycardia is common in the early post-CBS period, the acute effect of propranolol on DT was studied in an additional 14 such patients; propranolol 2·5 mg intravenously decreased HR (−19±2 [$P<0{\cdot}01$]) and increased DT (+158±23 ms [$P<0{\cdot}01$]). Chronic propranolol treatment or acute i.v. administration significantly increased DT/beat before and after CBS; this results in a longer time for coronary perfusion. Therefore, in addition to reducing myocardial oxygen consumption, propranolol may also improve myocardial oxygen delivery by increasing subendocardial flow and thus prevent subendocardial ischaemia.

38. A method for studying the carotid sinus baroflex in conscious rabbits

I. FARIS, J. IANNOS, G. JAMIESON and J. LUDBROOK, *Department of Surgery, The University of Adelaide, Australia*

It has not hitherto been possible to study, in conscious animals, the control of the circulation by the arterial baroreceptor reflexes. We have studied the carotid sinus baroreflex in rabbits after implanting a rigid capsule around an innervated carotid sinus. The opposite carotid sinus was denervated and both aortic nerves cut. Pressure within the capsule could be varied within the range of ±150 mmHg. The response of the blood pressure (MAP) and heart rate or its analogue the R–R heart interval to the induced changes in carotid sinus transmural pressure (CSTMP) has been studied. For the analysis of the results we have developed a curve-fitting programme which will describe the sigmoid stimulus-response curve and provide best estimates of both the limiting values of the curve and the maximum slope of the line. This latter value represents the sensitivity or gain of the reflex.

The capsules have been successfully implanted in 18 rabbits and the characteristics of the stimulus-response curve studied. In 11 of the animals the gain was a median 0·96 (range 0·64–2·28) mmHg/mmHg and the range of ΔMAP was a median 61 (47–30) mmHg. In the remaining 7 rabbits the values for gain and range were lower and the presence of additional functioning baroreceptors was demonstrated subsequently.

39. Effects of crossclamping of descending aorta

P. N. SYMBAS, M. H. DRUCKER, L. M. PFAENDER and C. H. HATCHER JUN., *Department of Surgery, Thoracic and Cardiovascular Surgery Division, Emory University School of Medicine, 69 Butler Street, SE, Atlanta, Georgia, USA*

The preferable techniques for surgical procedures requiring crossclamping of the descending aorta are still controversial. Two of these techniques were investigated in this study. In two groups of dogs the left atrial (LA), central venous (CV), carotid artery (CA), femoral artery (FA) and femoral vein (FV) pressures, urine output, thermal dilution cardiac output and ascending aorta, renal artery (RA) and CA blood flows were constantly recorded. Group 1 dogs were placed on FV to FA partial cardiopulmonary bypass, the descending thoracic aorta was then crossclamped and the initial flow of 60 ml min^{-1} kg^{-1} was adjusted to maintain the aorta precrossclamping LA pressure. The bypass was continued for 90 min. In group 2 dogs the descending aorta was similarly crossclamped without the use of bypass and the LA pressure and peripheral vascular resistance (PVR) proximal to the clamp were maintained at their pre-crossclamping levels by intravenous drip of sodium nitroprusside. The crossclamping of the aorta was maintained for 90 min. Blood samples were drawn every 30 min for the determination of epinephrine and plasma renin activity in both groups. LV, kidney and lung biopsies were obtained for electron microscopic studies 24 h postoperatively, at sacrifice. Mean stroke work (SW) and PVR for both groups were within 1 s.d. of each other during the 90 min aortic crossclamp period. CA, LA, CV and FV pressures could be maintained at baseline pre-crossclamp levels but renal blood flow decreased by approximately 60 per cent and there was no urine output during aorta crossclamping in both groups. The mean FA pressure in group 2 dogs decreased approximately 80 per cent. Plasma norepinephrine increased similarly in both but the increase of the epinephrine in group 2 was greater.

This study suggests that FV to FA partial cardiopulmonary bypass or i.v. infusion of sodium nitroprusside can be used with the same degree of safety during aorta crossclamping as long as the LA pressure and PVR are maintained at the preclamping level.

40. Transfer function analysis of common femoral artery Doppler waveforms

R. SKIDMORE, D. R. BIRD, J. P. WOODCOCK, P. W. DAVIES and R. N. BAIRD, *Departments of Medical Physics and Surgery, Bristol Royal Infirmary, Bristol*

The shapes of Doppler velocity-time wave forms obtained from the common femoral arteries of 44 limbs were defined by transfer functions (TF) damping, which is derived from Fourier analysis of the wave form shape, and is a sensitive indicator of proximal arterial stenosis (Skidmore and Woodcock, 1978).

Of 22 limbs with exercise or resting ischaemia and iliac artery stenoses shown by single-plane translumbar aortograms, TF damping (mean±s.d.) was significantly greater for major stenoses (minimum angiographic diameter <5 mm) than for minor stenoses of minimum diameter 5–8 mm (0·7±0·15 *v.* 0·5±0·07; $P<0{\cdot}001$, Mann–Whitney). Pulsatility index was also calculated but failed to discriminate between the two groups. A significant inverse relationship between TF and the degree of stenosis was established ($r=-0{\cdot}75$; $P<0{\cdot}000003$) so that minimum iliac artery diameter could be calculated from individual TF values.

Eleven age-matched asymptomatic control limbs (mean age 58 years) had less TF damping (0·38±0·05; $P<0{\cdot}001$) than the symptomatic limbs, and 11 younger normal subjects (mean age 32 years) have even less TF damping (0·31±0·03).

These results suggest that common femoral TF is a more sensitive measure of iliac artery stenosis than PI, and that TF and the degree of proximal artery stenosis are closely related. The increase in TF with age in normal subjects is of interest since it may indicate the progression of early atheromatous changes within the arterial wall.

41. Effectiveness and limitation of intra-aortic balloon counterpulsation in myocardial infarction in swine

J. LAAS, C. D. CAMPBELL, Y. TAKANASHI, RUTH PICK and R. L. REPLOGLE, *Division of Cardiac Surgery and Cardiology, Michael Reese Hospital and Medical Center and The University of Chicago, Chicago, Illinois, USA*

Intra-aortic balloon pumping (IABP) can reduce myocardial infarct size (MIS) in dogs, but this phenomenon may be secondary to pre-existing collaterals. This study describes haemodynamic changes, quantitates and qualifies myocardial infarction (MI) 24 h after coronary occlusion in swine, with and without IABP.

Twelve pigs had ligation of the LAD distal to the first diagonal branch. Six underwent 24-h treatment with IABP, beginning 45 min after occlusion. Haemodynamic effectiveness of IABP was analysed by switch on/off studies 1, 2, 3 and 24 h after ligation. Quantification of MIS was by histochemical staining with nitroblue tetrazolium; all infarcted areas were examined histologically.

In both groups MI reduced cardiac output (CO) (28·5 per cent) and mean aortic pressure (AOP) (20·4 per cent). Switch on/off studies showed a significant ($P<0·05$) improvement of AOP (4–6 per cent), CO (5–9·6 per cent) and a reduction of heart rate (4–7 per cent) during the switch on period. After 24 h, AOP in IABP animals (105±20 mmHg) was significantly ($P<0·01$) better than in controls (73±12 mmHg). MIS was 22·7±4·9 per cent of LV mass in controls and 19·4±5·9 per cent in IABP animals ($P>0·3$). Histologically, the appearance of ischaemic damage was indistinguishable between groups.

IABP is useful to stabilize and improve circulatory dynamics. However, in these controlled studies, a direct beneficial effect on acutely injured myocardium by reduction of the infarcting area could not be shown.

42. Fibrinolysis and the prediction of postoperative deep venous thrombosis

D. T. REILLY, A. C. BURDEN and D. P. POSSARD (Introduced by P. R. F. BELL), *Department of Surgery, Clinical Sciences Building, Leicester University, Leicester*

Fibrinolytic activity (FA) was examined in 89 non-smoking control subjects using the fibrin matrix test. The mean FA was 188·4 (±71) ng fibrinolysed $ml^{-1} h^{-1}$; the distribution was normal and continuous. The formation of a deep venous thrombosis (DVT) could result from decreased fibrinolysis or could secondarily increase fibrinolysis; 28 patients undergoing elective abdominal surgery were studied to see whether DVT developed in those whose FA fell outside 2 s.d.

Eighteen were non-smokers, 10 had stopped smoking before operation. FA was estimated preoperatively, postoperatively and at 24 and 48 h. For 5 days after operation a daily ^{125}I-fibrinogen uptake scan was performed. FA was measured in ignorance of the scan results.

FA preoperatively was 226 ng $ml^{-1} h^{-1}$ (range 0–689), postoperatively 243 ng $ml^{-1} h^{-1}$ (range 12–496), at 24 h 218 ng $ml^{-1} h^{-1}$ (35–699) and at 48 h 259 ng $ml^{-1} h^{-1}$ (39–689). FA in 9 patients fell outside 2 s.d. during the study, of these 7 developed a DVT. Two patients developed a DVT when FA was within the normal range. This is significant (Fisher's exact test $P=0·002$). No single assessment time was more accurate at predicting a DVT.

Assessment of FA can predict those patients developing a DVT in most cases.

43. The saline dilution test—a preoperative predictor of DVT risk

B. P. HEATHER, S. B. JANVRIN and R. M. GREENHALGH, *Department of Surgery, Charing Cross Hospital, London*

Certain factors, including the type of surgical operation, are associated with increased incidence of postoperative deep venous thrombosis (DVT). Recently (Janvrin et al., 1978), an association has been reported between the shortening of whole blood impedance clotting time, length of operation, rate of crystalloid fluid infusion and the postoperative DVT rate.

Preoperative blood samples were taken from 20 patients undergoing major abdominal surgery who were subsequently screened for DVT by the ^{125}I fibrinogen technique. Using the thrombelastograph, increased whole blood coagulability was demonstrated in all cases after *in vitro* dilution of the samples by 10–15 per cent with normal saline.

The 8 patients who developed a DVT had shown a mean coagulability increase of 55 per cent ± 16 per cent after *in vitro* saline dilution, whereas the 12 patients without evidence of DVT had shown a corresponding mean coagulability increase of 19 per cent ± 11 per cent. The difference between these mean values is highly statistically significant ($P<0·001$).

Of 10 patients with a coagulability increase on dilution of more than 30 per cent, 8 developed DVT, while none of the 10 patients with an increase of less than 30 per cent did so.

Thus, a single, rapid, preoperative *in vitro* test has identified those patients at risk of developing DVT after comparable abdominal surgery.

JANVRIN S. B., UR A. and GREENHALGH R. M. (1978) Postoperative deep vein thrombosis, an association with haemodilution. *Br. J. Surg.* **65**, 825.

44. Fluorocarbon emulsions as a blood substitute: effect on the omental microcirculation

B. ENDRICH, MARGARIDA TEIXEIRA and M. INTAGLIETTA, *Institute for Surgical Research, Klinikum Grosshadern, University of Munich, FRG, and Department of AMES—Bioengineering, University of California, San Diego, USA*

Red blood cell (RBC) velocity, vessel diameter and arteriolar pressure were determined in the microcirculation of the rabbit omentum after isovolaemic blood replacement by means of different fluorocarbon emulsions. The measurements were carried out at different haematocrit levels utilizing television techniques *in situ*.

The administration of a 15 per cent (by volume) $C_8F_{17}B_r$ or FC-47 fluorocarbon emulsion caused a slight drop of the mean arterial pressure, temporary arteriolar constriction, temporary decrease of arteriolar pressure and a localized decrease of RBC-velocity in postcapillaries and collecting venules.

Table I: VALUES IN POSTCAPILLARIES BEFORE AND AFTER BLOOD SUBSTITUTION BY MEANS OF DIFFERENT FLUOROCARBON EMULSIONS

	Control	Blood exchange 30 ml/kg BW
10% FC-43 ($n=7$)		
Hct (%)	41·2±0·8	24·8±1·4
P_A (cmH_2O)	49·5±4·1	52·0±9·9
V_{RBC} (mm/s)	1·2±0·1	1·3±0·2
15% $C_8F_{17}B_r$ ($n=7$)		
Hct (%)	42·8±1·5	29·[illegible]±1·4
P_A (cmH_2O)	45·7±1·5	40·0±4·2
V_{RBC} (mm/s)	0·8±0·1	0·4±0·1
15% FC-47 ($n=7$)		
Hct	48·2±2·0	27·7±3·6
P_A (cmH_2O)	44·2±6·3	36·6±8·4
V_{RBC} (mm/s)	1·0±0·2	0·5±0·1

Mean values±s.e. mean.

Hct, Haematocrit; P_A, arteriolar pressure; V_{RBC}, erythrocyte velocity.

Damage of endothelial cells, as suggested by augmented sticking of leucocytes along the wall of collecting venules, and destruction and conglomeration of red blood cells, were consistently observed in capillaries after injection of both of the 15 per cent fluorocarbon emulsions, whereas the injection of a 10 per cent FC-43 emulsion did not induce any significant macrohaemodynamic and microvascular alterations.

Our findings indicate that higher concentrated fluorocarbon emulsions cause deterioration of microhaemodynamic function and damage to endothelial and blood cells.

It is concluded that the fluorocarbon emulsions tested do not yet fulfil the basic requirements for a blood substitute.

45. Release of lysosomal hydrolases during extracorporeal circulation

V. P. ADDONIZIO, L. K. CHANG, J. R. STRAUSS III, R. W. COLMAN and L. H. EDMUNDS JUN., *Departments of Surgery, Obstetrics and Gynecology, and Medicine, University of Pennsylvania, Philadelphia, Pennsylvania 19104, USA*

Contact with synthetic surfaces results in platelet adhesion and release of granule contents. This study demonstrates that during extracorporeal circulation, release of lysosomal hydrolytic enzymes occurs concomitantly. When fresh, heparinized human blood (500 ml) was recirculated for 2 h at 1000 ml/min at 37 °C in silicone rubber circuits ($n=16$) containing a membrane oxygenator (0·85 m^2), plasma levels of the platelet specific protein LA-PF4 rose from <0·5 to 15±2 μg/ml plasma ($P<0·01$), indicating extensive release of platelet α-granule contents. Concurrently, plasma activity of the lysosomal hydrolytic enzyme, N-acetyl-B-glucosaminidase, increased fourfold to 30±5 pmol substrate hydrolysed $ml^{-1} min^{-1}$ ($P<0·01$). Absorbed albumin, which decreases polymer surface affinity for platelets, and prostaglandins E_1 and E_2, which are potent inhibitors of platelet function, prevented release of LA-PF4 but failed to alter hydrolase release. Lidocaine (10 μg/ml), however, a membrane stabilizing agent, effectively inhibited lysosomal enzyme release without altering secretion of LA-PF4. The fact that platelet inhibitors failed to block secretion of lysosomal enzymes while lidocaine effectively prevented hydrolase release without altering LA-PF4 secretion suggests that leucocytes, not platelets, are the source of released lysosomal enzymes. Release of hydrolytic enzymes during cardiopulmonary bypass may cause endothelial cell injury and thus contribute to the increased vascular permeability associated with extracorporeal circulation.

46. Platelet preservation during cardiopulmonary bypass with prostaglandins

J. J. A. M. VAN DEN DUNGEN, J. C. Z. DE JONG and CH. R. H. WILDEVUUR, *Department of Experimental Surgery, University Hospital, Oostersingel 59, 9700 RB Groningen, The Netherlands*

The postoperative bleeding tendency in cardiac surgery is associated with decreased platelet numbers and impaired platelet function. During CPB the platelets adhere to the non-physiological surfaces and are continuously induced to aggregate, which leads to impaired function and to thrombocytopenia. The capacity of the potent platelet inhibiting drugs prostaglandin E_1 (PGE_1) and Prostacyclin (PGI_2) to prevent platelet aggregation during CPB and to preserve platelet function and numbers for optimal haemostasis after CPB was studied in canine experiments. In the control experiments ($n = 6$) using a bubble oxygenator, platelet numbers decreased postoperatively to 43 per cent of their preoperative value ($241 \pm 31 \cdot 10^9$/l). With PGE_1 treatment ($n = 6$), given during CPB, platelet numbers could be maintained at 74 per cent ($P < 0.02$) and with PGI_2 treatment ($n = 6$) even at 93 per cent ($P < 0.01$). Differences remained significant until the third postoperative day.

Platelet function (ADP induced aggregation) decreased in the control experiments to about 20 per cent shortly after CPB. With prostaglandin treatment platelet function was effectively inhibited during CPB but restored shortly thereafter in both groups to 70 per cent of the preoperative value ($P < 0.01$). Bleeding times, 2 h after CPB, were severely lengthened (>15 min) in the control group, while in the treated groups only slightly prolonged (6< min) values were observed.

In conclusion, administration of PGE_1 or PGI_2 during CPB can protect platelets to a large extent from irreversible damage and has great promise for clinical application in CPB to preserve optimal haemostasis.

47. Preoperative ^{99}Tc^{m}-antimony sulphide colloid scintigraphy for identification of the lymph drainage in patients with malignant melanoma

P. E. JONSSON, S. E. STRAND, S. DAWISKIBA, L. HAFSTRÖM and B. PERSSON, *Departments of Surgery, Radiation Physics and Pathology, University of Lund, S-221 85 Lund, Sweden*

The direction of lymphatic drainage from skin tumours, especially those situated on the trunk, is variable. Lymphangiography, because of technical problems, is not always possible. An alternative technique is scintillation camera imaging after subcutaneous injection of ^{99}Tc^{m}-labelled antimony sulphide colloid (Aspergren et al., 1978). This method has been assessed in 9 patients with malignant melanoma, 5 on the trunk and 4 on the lower limb. A subcutaneous injection of 0·5 ml colloid (particle size 5–15 mm) was made around the scar of the excised trunk melanoma and on the dorsum of the foot of the limb melanoma. As a control, a similar injection was performed on the other side of the body. The uptake of the colloid by regional lymph nodes was monitored by sequential images taken at 15-s intervals. Further pictures were taken 4 h after the injection. A block dissection of the regional lymph nodes was performed within 24 h of the study; the radioactivity of each node was measured, and correlated with the histopathology.

Radioactivity was detected in regional lymph nodes 15 min after injection. Reduced uptake, compared with the contralateral side, suggested metastases. The rate of uptake by the nodes was higher on the affected side in half the patients. The uptake by the individual node was 2–5 per cent. The total uptake of diseased nodes was reduced at 4 h and at the time of operation.

It is concluded that lymphoscintigraphy is a practical method of assessing lymph node metastases in patients with malignant melanoma.

ASPERGREN K., STRAND S. E. and PERSSON R. B. R. (1978) Quantitative lymphoscintigraphy for detection of metastases to the internal mammary lymph nodes. Biokinetics of ^{99}Tc^{m} sulphide colloid uptake and correlation with microscopy. *Acta Radiol. Oncol.* **17**, 17–26.

48. The relationship between hormone receptors and cell kinetics in breast tumour

T. COOKE, D. GEORGE, K. GRIFFITHS and R. SHIELDS, *Department of Surgery, Liverpool and Tenovus Institute, Liverpool*

The potential growth rates in breast carcinomas have been investigated and the results related to the presence of hormone receptors.

Tumour fragments, 1 mm^3, were incubated with ^{3}H thymidine under hyperbaric conditions. The uptake of the radioactive label by the tumour was detected by autoradiography and a thymidine labelling index (TLI), which represents the percentage of epithelial cells labelled, was calculated. Oestrogen (ER) and progesterone (PR) receptors were determined by the dextran-coated charcoal technique. The results were compared by *t* tests.

The mean TLI in 56 tumours investigated was 5·11 per cent. In tumours without receptors (ER−, PR−) the mean TLI was 10·85 per cent. This was significantly higher ($P < 0.001$) than the mean TLI of 1·63 per cent in tumours that had both receptors present (ER+, PR+). An initial analysis had shown that ER+ tumours with levels of receptor below 50 pmol/g protein had a TLI with a mean of 3·59 per cent. A similar intermediate range of TLI with a mean of 4·23 per cent was found in ER+, PR− tumours.

These results confirm those of the previous report (Meyer et al., 1977) that tumours with low or absent levels of ER had high cellular proliferation rates. Our study shows that by using both PR and ER the tumours can be divided into groups with high (ER−, PR−), low (ER+, PR+) and intermediate (ER+, PR−) rates of cellular proliferation.

The high TLI, reflecting a high potential growth rate in tumours without receptors, may explain in part that early breast tumours without ER are associated with early recurrence.

49. A central mechanism for anorexia in cancer—role of the neurotransmitter, serotonin

R. KRAUSE, J. M. GREEP and J. E. FISCHER, *Department of Surgery, State University Hospital of Limburg, Maastricht, The Netherlands*

Anorexia in malignant neoplastic disease is an early sign and may occur before the development of a significant host tumour burden, suggesting a central mechanism that interferes with appetite and satiety regulation. Recent (neuropharmacologic and neurophysiologic) studies have established the role of serotonin (5HT), a neurotransmitter and product of tryptophan (TRP), in the regulation of feeding behaviour.

In the following study, TRP and 5HT metabolism and anorexia were studied in tumour-bearing rats. Three groups of rats (80–100 g) were used.

Walker 256 carcinosarcoma cells were injected into the hind limb (group 1) and saline into controls (groups 2 and 3). Groups 1 and 2 were freely fed while group 3 was pair-fed the same amount of food eaten by group 1 the previous day. Animals were sacrificed 10 days after injection; blood and brain amino acids, brain serotonin turnover and factors influencing this were measured. Voluntary food intake in group 1 decreased as early as 3 days after injection, at which time the tumour was not palpable. Plasma TRP was decreased in group 1 *v.* group 3 (67 *v.* 86 mmol/l, $P<0{\cdot}001$). However, brain TRP was normal in group 1 (21±1 nmol/g) instead of decreased as one would have expected according to the low plasma levels. In group 3, however, brain TRP values were low and in concordance with expected values: 14±1 nmol/g; $P<0{\cdot}001$. Brain serotonin metabolism was proportionally altered with TRP levels. From serotonin point of view, the tumour rats were 'satiated' (or anorectic) while the pair-fed animals were 'hungry'. The mechanism of increased brain TRP in tumour rats related to increased plasma free TRP secondary to decreased albumin and increased free fatty acid levels.

Preliminary results on decreasing brain serotonin activity in subsequent experiments, proved to increase food intake. These findings may convert the problem of anorexia in cancer to a treatable condition.

50. Circulating breast tumour antigen-sensitive T lymphocytes in early breast cancer and high risk benign breast disease

W. G. RAMEY, G. A. HASHIM and H. F. FITZPATRICK, *Department of Surgery, St Luke's Hospital Center and Columbia University, New York, USA* (*see* pp. 848–852)

51. Ultrasonography in the diagnosis of breast disease

W. R. LEES (Introduced by R. C. G. RUSSELL), *Department of Clinical Measurement, The Middlesex Hospital, London*

Ultrasound examination of the breast using purpose-designed machines has been shown to give a diagnostic accuracy similar to X-ray mammography (Pluygers et al., 1977). This study was undertaken to determine if standard machines could give a similar accuracy in a group of 132 unselected referrals (carcinoma 30, biopsy-proved benign disease 36, normal 66). Seventy of these patients had X-ray mammography (carcinoma 21, biopsy-proved benign disease 15, normal 34).

The ultrasonographic criteria of malignancy were sharp definition and irregularity of the margins of the lesion, internal inhomogeneity, low reflectivity, strong beam attenuation and disturbance of surrounding anatomy. The lesion was reported as being definite cancer, suspicious of cancer, benign, a simple cyst or normal. The usual criteria for cancer were used in mammography (Gallagher and Martin, 1969), and a similar reporting scheme adopted.

Ultrasound diagnosed 26 of 30 cancers (86 per cent), and 2 were suspicious of cancer (total detection rate 93 per cent). One cancer was reported as benign and the other was not detected (tumour 5 mm diameter, also missed by mammography). The mammographic results were definite cancer 15 (71 per cent), suspicious of cancer 4 (86 per cent) and 2 not detected. All cysts were correctly diagnosed by ultrasound.

It is concluded that ultrasound examination of the breast is as accurate as X-ray mammography, and has the advantage of avoiding exposure to radiation.

GALLAGHER S. H. and MARTIN J. E. (1969). The study of mammary carcinoma by mammography and whole organ sectioning. *Cancer* **23**, 855–873.

PLUYGERS S. E., ROMBAUT M., BEAUDUIN M. et al. (1977) Possibilités, résultats et indications de l'échographie mammaire. *J. Belge Radiol.* **60**, 181–196.

52. Effect of jaundice on post-cholecystectomy bile lipid secretion

P. R. BAKER and C. CUSCHIERI, *Department of Surgery, Ninewells Medical School, University of Dundee, Dundee*

The bile lipid secretory response to interruption of the enterohepatic circulation following cholecystectomy, exploration of the common bile duct and T tube drainage has been studied in 14 patients with preoperative jaundice (group J) (serum bilirubin 23–335 μmol/l) and in 14 non-jaundiced patients (group NJ). Twenty-four hour bile volumes were collected for up to 12 days after operation and analysed for individual and total bile salts (BS), cholesterol (CH) and phospholipid (PL).

There was no significant difference in the daily bile volumes of the two groups. However, group NJ secreted increasingly higher amounts of BS, CH and PL than group J. The increased total bile salt output was due to the presence of primary bile salts, indicating increased hepatic synthesis. Maximum bile lipid outputs usually occurred after the sixth postoperative day and were significantly higher in group NJ. The mean daily output of all three bile lipids increased linearly from the second postoperative day in both groups, but the rates of increase (regression coefficients, *b*) in μmol 24 h^{-1} d^{-1} were significantly higher in group NJ.

	Maximum output (mmol/24 h) mean±s.e. mean	Rank sum test
BS		
NJ ($n=14$)	9·45±0·96	$P<0{\cdot}002$
J ($n=14$)	3·14±0·35	
CH		
NJ ($n=11$)	1·75±0·18	$P<0{\cdot}002$
J ($n=12$)	0·66±0·07	
PL		
NJ ($n=9$)	2·37±0·33	$P<0{\cdot}002$
J ($n=11$)	0·79±0·10	

	Rate of increase in output (μmol/24 h^{-1} d^{-1}) b+s.e. mean	t test
BS		
NJ ($n=14$)	808±100	$P<0{\cdot}001$
J ($n=14$)	262±34	
CH		
NJ ($n=11$)	104±20	$P<0{\cdot}001$
J ($n=12$)	14±8	
PL		
NJ ($n=9$)	154±35	$P<0{\cdot}02$
J ($n=11$)	66±10	

The results suggest an impairment in the reserve for hepatic synthesis and/or secretion of bile lipids in patients with jaundice due to large duct obstruction and indicate the need for early surgical decompression.

53. Portacaval shunt and arterialization of the liver: haemodynamic investigations and clinical results

J. B. OTTE, M. REYNAERT B. DE HEMPTINNE, B. GRIBOMONT, A. GEUBEL, L. LAMBOTTE and P. J. KESTENS, *Cliniques St Luc, Université Catholique de Louvain, Avenue Hippocrate 10, 1200 Bruxelles, Belgium*

The clinical experience of arterialization of the liver reported by other centres has not given clear information on three important points: selection of the patients who could benefit from the procedure, operative mortality in emergency cases, length and quality of survival.

A programme of peroperative haemodynamic investigation was developed which included recording of (*a*) pressure in the portal vein—free portal pressure (FPP), maximum perfusion pressure (MPP), hepatic arterialized portal pressure (HAPP); (*b*) corrected sinusoidal pressure (CSP) at various stages of operation—the difference between the values recorded with the portal vein open or occluded gave the ΔCSP; (*c*) flow in the hepatic portal bed before (Q_{pv}) and after ($Q_{art\text{-}pv}$) portacaval shunt with arterialization (PCS-ART); (*d*) resistance of the hepatic portal bed which was calculated from the data of flow and pressure. This programme was achieved in 28 patients whose results are studied. The second part of the study was conducted between September 1973 and November 1978: 51 patients (27 elective and 24 emergency) were found at peroperative investigation to have a high residual portal flow and were submitted to PCS-ART; the operative mortality, long term survival and encephalopathy were recorded in this group.

Haemodynamic results: the flow and pressure recordings allowed separation of patients in two subgroups: (*a*) stagnant portal flow (6 patients): Q_{pv} = 83±27 ml/min; MPP =

$4{\cdot}4\pm1{\cdot}7$ cmH$_2$O; ΔCSP $= 0{\cdot}67\pm0{\cdot}33$ mmHg; (*b*) high portal flow (22 patients): $Q_{PV} = 538\pm50$ ml/min; MPP $= 25\pm1{\cdot}7$ cmH$_2$O; portal bed resistance $= 2{\cdot}45$ dyn s^{-1} cm^{-5}. There was a good correlation between the portal flow and (*a*) the MPP ($r = 0{\cdot}72$; $P<0{\cdot}001$, (*b*) the ΔCSP ($r = 0{\cdot}86$; $P<0{\cdot}001$). After arterialization, which was reserved for patients of subgroup (*b*), the flow and the pressure in the hepatic portal bed were reduced by one-third ($Q_{art-PV} = 354\pm35$ ml/min; HAPP $= 30{\cdot}5\pm1{\cdot}2$ cmH$_2$O) while the ΔCSP remained unchanged ($14{\cdot}6\pm0{\cdot}92$ mmHg) as well as the resistance of the hepatic portal bed ($2{\cdot}65$ dyn s^{-1} cm^{-5}).

Clinical results: Operative mortality was not affected in elective cases but was drastically reduced in emergency cases (17 per cent). In patients operated electively, the actuarial survival rate remained at 85 per cent from the first to the sixth postoperative year; in patients operated on as an emergency, the survival rate dropped from 73 to 67 per cent from the first to the third postoperative year to stabilize at 52 per cent from the fourth to the sixth postoperative year. Among 31 long term survivors (over 6 months), severe encephalopathy was almost exclusively seen in alcoholics who resumed drinking (16 per cent). These results are significantly better than those of a previous group of 48 patients submitted to PCS alone (23 elective, 25 emergency).

54. The role of histamine in biliary tract motor function in the primate

D. H. BIRKETT, W. E. WISE, W. W. LAMORTE, D. J. SCHOETZ, J. M. GACA and L. F. WILLIAMS, *Division of Surgery, Boston University Medical Center, Boston, USA*

The importance of histamine in gastric secretion is well documented but a possible role for histamine as a mediator of biliary motor function has not yet been appreciated. Unpublished *in vitro* experiments in our laboratory demonstrated that histamine causes contraction of guinea-pig gallbladder muscle by stimulation of H$_1$-receptors; administration of an H$_2$-agonist produced relaxation. Studies presented here demonstrate that histamine influences gallbladder pressure (GBP) and choledochal sphincter resistance (CSR) in a reciprocal manner.

Awake baboons were used to measure changes in GBP and CSR in response to histamine, its agonists and antagonists.

Intravenous histamine increases GBP with a parabolic dose–response relationship ($n = 416$). Pretreatment with the H$_1$-antagonist diphenhydramine depressed the response to histamine at all doses ($n=81$; $P<0{\cdot}001$). Pretreatment with the H$_2$-antagonist metiamide increased the response to histamine ($n = 199$; $P<0{\cdot}005$). The H$_1$ agonist 2-pyridylethylamine (PEA), given intravenously, elevated GBP in a parabolic dose–response relationship. The H$_2$-agonist (S-(3-(N,N-dimethylamino)propyl) isothiourea (dimaprit) did not change GBP in the doses studied.

A 10-min infusion of histamine decreased CSR ($n = 5$; $P<0{\cdot}05$) with a concomitant rise in GBP. Intravenous infusion of PEA increased GBP but did not change CSR. While histamine's ability to raise GBP is mediated by H$_1$-receptors, the concomitant fall in CSR is probably mediated by H$_2$-receptors.

These data demonstrate well-defined biliary motor responses to histamine and its H$_1$ and H$_2$ components; they suggest a physiologically important role in coordinating biliary responses.

55. The choledochal pressure profile in normal and postoperative conditions; an experimental study in 36 mongrel dogs

E. BRUIJNES and P. J. KLOPPER, *Department of Surgical Research, Academic Hospital Wilhelmina Gasthuis, Amsterdam, The Netherlands*

In clinical urology urethral pressure measurement has become a valuable method in detecting urethral obstruction or incontinence of the sphincter. In biliary surgery peroperative radiomanometry has been studied comprehensively. In order to evaluate manometry as an eventual clinical method, to be used pre- and peroperatively, choledochal pressure manometry (CPR) was performed in 15 (anaesthetized) mongrel dogs. In accordance with the standards, advised by the International Continence Society, electronic pressure measurements were made with a 6 French polyethylene catheter, supplied with two side holes and perfused with 2 ml of saline per minute. This catheter was withdrawn with a constant velocity of 7 mm/min. The pressure profiles were analysed every 5 mm, the duodenal pressure being taken as a reference point. The mean normal pressure amounted to $10{\cdot}9\pm2{\cdot}2$ mmHg (mean ± s.e. mean). At the choledochoduodenal junction a statistically significant biphasic rise of pressure was recorded, $59{\cdot}8\pm8{\cdot}5$ and $54{\cdot}3\pm7{\cdot}2$ mmHg. The total length of the biphasic graph was $5{\cdot}5\pm0{\cdot}3$ cm, the distal peak measured $1{\cdot}6\pm0{\cdot}1$ cm. The proximal peak was located at $3{\cdot}7\pm0{\cdot}3$ and the distal at $1{\cdot}0\pm0{\cdot}1$ cm from the orifice of the papilla. This study in normal common bile ducts was continued with a second investigation in 21 animals, divided into three groups. In group 1 (8 animals) the sphincter was dilated. In group 2 (5 animals) sphincteroplasty was performed, while group 3 (8 animals) had a diathermic sphincterotomy. In all groups the treatment was followed by a distinct decrease in height and length of the pressure profile; all measurements were repeated after a period of 2 months. In the first group dilatation was followed by a decrease of pressure from $55{\cdot}5\pm7{\cdot}5$ to $12{\cdot}9\pm5{\cdot}8$ mmHg and of length from $5{\cdot}2\pm1{\cdot}1$ to $1{\cdot}6\pm0{\cdot}5$ cm. After 2 months the values increased significantly to about half of the initial data. Also in the second group length and pressure decreased significantly. After 2 months the pressure amounted to $9{\cdot}2\pm3{\cdot}4$ mmHg and $1{\cdot}7\pm0{\cdot}4$ cm. In the third group diathermic sphincterotomy resulted in a pressure fall to $8{\cdot}5\pm4{\cdot}1$ mmHg and a length of $1{\cdot}7\pm0{\cdot}4$ cm ($P<0{\cdot}05$). After 2 months these values were $19{\cdot}6\pm7{\cdot}3$ mmHg and $1{\cdot}3\pm0{\cdot}2$ cm respectively. The functional data correlate well with the morphological structure as studied with histology, microradioangiography and polymeric casts. The present study shows that CPR can give valuable information on pressure, length and form of the profile of the sphincter. Surgical intervention is followed by a loss of the biphasic character of the graph. The values obtained in groups 2 and 3 show that both methods give an effective decrease of length and pressure. The technique can be performed during endoscopy in man.

56. Kinetics of BSP clearance as the most reliable criterion of the hepatic dysfunction after jejuno-ileal bypass in the rat

J. MARESCAUX, C. STOCK, M. O. HOFF, G. COUMAROS, JIMENEZ GARCIA and J. F. GRENIER, *Inserm Unite 61, 3 avenue Molière, 67200 Strasbourg Hautepierre, France*

Hepatocellular failure is the most serious complication of intestinal bypass surgery. Numerous aetiologic factors have been advanced to explain these lesions but the criteria used are not quite reliable. The purpose of this work is to establish the best parameter of hepatic dysfunction in the adult Wistar rat and to correlate its variations with the evolution of the intestinal adaptation.

Two hundred and forty-four adult Wistar rats, weighing 290 g, were randomly divided into two groups. After ether anaesthesia, group 1 (123 rats) was submitted to a 90 per cent small intestinal bypass with an end to end jejuno-ileal anastomosis. The excluded loop was closed and the distal extremity anastomosed end to side to the sigmoid. Group 2 (121 control rats) was sham-operated. The studies were performed every 15 days until the third month after operation. The following parameters were determined as indices of liver function: kinetics of BSP clearance from the plasma; glutamic oxaloacetic transaminase (GOT); glutamic pyruvic transaminase (GPT); esterase A and C; cholinesterase C; plasma total protein and albumin. Simultaneously, the liver was examined by optic and electron microscopy. Intestinal adaptation of the included segment was studied by measuring the wet weight of the mucosa and its protein content.

There were no structural or ultrastructural changes in the liver of both groups. Animals of group 1 showed a marked decrease of plasma total proteins and albumin, which was the most pronounced at 1 month (125 per cent of control, $P<0{\cdot}01$). There was no difference in the plasma enzyme activities measured in both groups. The percentage of retention of BSP was increased in group 1 up to 2 months, the maximal increase (310 per cent of control, $P<0{\cdot}01$) being observed at 1 month. The wet weight of the ileal mucosa and its protein content, expressed per unit length, were not different up to 2 months; from this period, both parameters increased by approximately 160 per cent of control ($P<0{\cdot}05$).

These results show that BSP clearance is the most sensitive and reliable criterion of the hepatic dysfunction in Wistar rats while plasma enzyme activities were not altered after jejuno-ileal bypass. The parallelism between the variations of the BSP clearance and the absence of a sufficient intestinal adaptation lends weight to the 'nutritional' theory of hepatic lesions which occur after jejuno-ileal bypass. Indeed, within the initial postoperative period, there is a malabsorption syndrome that induces a transient malnutrition state.

57. The determination of site and severity of arterial lesions in claudicants using ^{99}Tc^{m} muscle clearance

N. ANGELIDES and A. NICOLAIDES, *Vascular Laboratory, Cardiovascular Unit and Academic Surgical Unit, St Mary's Hospital, London*

There has been no end to the attempts made to determine the site and severity of arterial lesions in claudicants by the use of non-invasive methods, but, so far, their diagnostic value has been limited. A method whose diagnostic accuracy in determining the site and functional severity of arterial lesions approaches that of arteriography is presented.

The hyperaemic index, which is the ratio of the total excess of blood during post-exercise hyperaemia over the maximum hyperaemic flow, has been determined in the thigh and calf simultaneously by measuring the ^{99}Tc^{m}-muscle clearance in 30 limbs of 20 healthy volunteers and 139 limbs of 145 patients with claudication. Lumbar arteriography classified the lesions in all the patients as 0–10 per cent, 10–40 per cent, 40–70 per cent, <70 per cent stenosis or occlusion.

A bivariate analysis of the hyperaemic indices of the thigh and calf determined the site and severity of single lesions with 100 per cent accuracy. In limbs with combined aorto-iliac and superficial femoral lesions the values of the hyperaemic indices could determine which of the two lesions was the more severe (100 per cent accuracy) and the degree of stenosis produced by each one (96 per cent accuracy).

These findings have been confirmed in a second blind prospective study of 44 limbs in which determination of the site and severity of lesions has preceded aortography.

58. Thromboxane A_2 regulation of renal vascular resistance

C. B. ANDERSON, G. A. SICARD and E. E. ETHEREDGE, *Department of Surgery, Washington University School of Medicine, St Louis, USA*

The adverse effect on renal vascular resistance (RVR) of non-ischaemic kidneys by ischaemic kidneys when both share a common perfusate can be prevented by imidazole inhibition of thromboxane A_2(TXA_2) synthesis (Sicard et al., 1978). Paired dog kidneys were perfused on two MOX-100 machines connected to a pool of common perfusate. To an optimally harvested first kidney was added a second kidney from each of 7 groups. Group 1 (control) second kidney optimally harvested; groups 2–7, second kidney subjected to 60 min of warm ischaemia. Group 2, no additional manipulation; group 3, ischaemic kidney on perfusion for only 10 min; group 4, ischaemic kidney added after 1 h of separate perfusion; group 5, imidazole (7·5 mg/kg, i.v.) treatment of both kidneys; group 6, imidazole treatment of first non-ischaemic kidney only; group 7, imidazole treatment of second ischaemic kidney only. The percentage increase in baseline RVR of non-ischaemic first kidneys after addition of second kidneys is shown below.

	Groups						
Time (h)	1	2	3	4	5	6	7
½	3	37	29	—	2	−12	−17
1	5	56	55	−4	11	−13	11
2	5	76	69	−2	22	−12	28
3	2	86	80	—	48	−9	39

We conclude that the site of production and action of TXA_2 occurs in both kidneys but is more important in the non-ischaemic kidney since limited exposure to the initial venous effluent of the ischaemic kidney causes a sustained rise in RVR which can be most effectively blocked by TXA_2 inhibition in the non-ischaemic rather than in the ischaemic kidney. Unmasking of prostaglandin E_2 (renal vasodilatation) by TAX_2 inhibition may contribute to this effect.

SICARD G. A., ETHEREDGE E. C. and ANDERSON C. B. (1978) Modification of ischaemic renal injury by prostaglandin inhibition. *Surg. Forum* **29**, 54–56.

59. Effects of extracranial–intracranial anastomosis on cortical oxidative metabolism

G. AUSTIN, B. CHANCE, C. BARLOW and R. JUTZY, *Section of Neurosurgery, Loma Linda University School of Medicine, Loma Linda, California, and Johnson Research Foundation, University of Pennsylvania, Philadelphia, USA*

Results of 163 microanastomoses of the superficial temporal (STA) to middle cerebral artery (MCA) in patients with transient ischaemic attacks (TIA) or minor stroke show a 15 per cent to 20 per cent increase in cortical blood flow (i.v. ^{133}Xe method). To explain improvement in TIA and neurological deficit, it is also necessary to provide evidence for increased cortical oxidative metabolism. Experiments were done on 43 cats to monitor brain Po_2 (bPo_2) and the redox level of members of the electron transport chain, using N_2O/O_2 anaesthesia (FiO_2 20 per cent), with immobilization by Flaxedil, plus local skin anaesthesia, ketamine and artificial ventilation. Cortical cytochrome oxidase (Cy$_3$. a a$_3$) and flavoprotein (FP) levels were monitored by non-invasive optical techniques.

Model TIA produced by 5–30 s bilateral common carotid occlusion (CCO), caused decreased bPo_2 and reduction of Cyt. a,a$_3$ and FP. Hypotensive ischaemia (arteriotomy) or hypoxia (Fio$_2$ 10 per cent) caused decreased bPo_2 and reduced Cyt. a,a$_3$ to be greatly prolonged following a test CCO. The same monitoring techniques were used intraoperatively in 37 patients. Following anastomosis there was an increase in bPo_2 and oxidized Cyt. a,a$_3$ and FP, as well as more rapid recovery from a test change in Fio$_2$ (15 per cent). These results suggest increased cortical oxidative metabolism as the major source of clinical improvement.

60. Deep vein thrombosis and tourniquet ischaemia

N. A. G. JONES, P. S. F. CHAN, P. J. WEBB, F. MISTRY and V. V. KAKKAR, *Thrombosis Research Unit, King's College Hospital Medical School, London*

Operations on the lower limb are frequently performed in a bloodless field. However, it is not known whether the use of a tourniquet increases the likelihood of a thrombus formation by promoting venous stasis or reduces the incidence by increasing the fibrinolytic activity as a result of release of the plasminogen activator produced in the endothelium of small vessels.

Fifty-five consecutive patients (mean age 42 years, range 18–87), undergoing lower limb surgery requiring the use of a pneumatic tourniquet, were investigated. Venography was performed in each patient on the seventh postoperative day to confirm or refute the presence of deep vein thrombosis (DVT). In 13 consecutive patients, blood samples were withdrawn from an arm vein just before induction of anaesthesia, after 30 min of tourniquet ischaemia, immediately after release of tourniquet and on the second postoperative day. These were analysed for changes in the fibrinolytic activity by measuring the levels of plasminogen, fibrinogen, euglobulin lysis time (ELT), fibrinogen/fibrin degradation products (FDP), α_1-antiplasmin and α_2-macroglobulin. The operations performed included meniscectomy (37 patients), knee replacement (9 patients) and minor foot operations (9 patients). Twenty-one (38 per cent) out of 55 patients developed DVT; in patients below the age of 40 the incidence was 26 per cent and over 40 years, 50 per cent. Eighteen tibial thrombi were >5 cm, 3 of these involved the popliteal or femoral vein. One of 3 smaller thrombi (<5 cm) was associated with femoral cusp thrombosis. Of all the haematological investigations performed, the only change of significance was a prolonged ELT at 48 h ($P<0·02$).

61. A randomized trial of heparin *v.* streptokinase in the treatment of acute proximal venous thrombosis

M. S. ELLIOT and THE GROOTE SCHUUR HOSPITAL THROMBO-EMBOLUS STUDY GROUP (Introduced by J. TERBLANCHE), *Groote Schuur Hospital and the University of Cape Town* (*see* pp. 838–843)

62. What length of prepyloric stomach should be left innervated in highly selective vagotomy?

D. JOHNSTON, P. J. LYNDON, M. J. GREENALL, A. BAKRAN and A. T. R. AXON, *University Department of Surgery and Gastroenterology Unit, General Infirmary, Leeds*

Johnston and Wilkinson (1969) leave 6 cm (5–7) of distal stomach innervated during HSV, but Amdrup and Jensen, by the use of a pH probe were able to leave 8–10 cm (mean, 9 cm) innervated and found only half the incidence of postprandial fullness which was found in Leeds and a higher proportion of Visick grade 1 results (Amdrup et al., 1974). This might have been due to better accommodation to distension after the lesser gastric denervation. Goligher (1974) subsequently stated that he left 10–11 cm innervated.

In a prospective, randomized trial in 90 DU patients, we left 6 cm (5–7 cm) innervated in 44 patients and 10 cm (9–11 cm) innervated in 42 patients. Patients were then reviewed 'blind' in a follow-up clinic, each year for 3–6 years. Operative mortality was nil.

	6 cm	10 cm
Hollander positive test (1 week)	18% (2% early positive)	37% (21% early positive)
Recurrent ulceration (RU)	9%	13%
Epigastric fullness p.c.	24%	22%
Poor results (Visick grades 3 and 4)	18%	26%

Differences not significant except for PAO_I–BAO.

When 10 cm were left innervated, both mean PAO_I and RU were higher and more patients were suspected of having RU. Side effects of operation such as fullness, flatulence and heartburn were just as common after the more limited gastric denervation. Thus it seems preferable to leave only 5–7 cm innervated.

AMDRUP E., JENSEN H. E., JOHNSTON D. et al. (1974) Clinical results of parietal cell vagotomy (highly selective vagotomy) two to four years after operation. *Ann. Surg.* **180**, 279–284.

63. The effect of bile acids on the pancreatic duct mucosal barrier

H. A. REBER and J. G. MOSLEY, *Surgical Service, VA Medical Center, and Department of Surgery, University of Missouri, Columbia, USA*

Back diffusion of HCO_3^- from pancreatic juice into blood is impaired by a barrier in the pancreatic duct. We previously showed that certain agents damage this barrier (Reber et al., 1979). Since pancreatitis and pancreatic cancer may be related to bile reflux into the pancreatic ducts, we studied the effects of bile acids on this barrier. We perfused the main duct in cats at 0·5 ml/h and pressure <20 mmHg, for two periods (1 and 3) using a standard perfusate (SP) (Na 150, HCO_3 120, Cl 30 mmol/l). Periods 1 and 3 were separated by period 2 when the duct was perfused with bile acid in SP. An increase in back diffusion of HCO_3^- in period 3 compared to 1 was interpreted as an increase in mucosal permeability from damage during period 2.

No. of cats	Bile acid (period 2)	Period 3 *v.* Period 1 ΔHCO_3 Flux	ΔCl Flux
10	Control	+0·09±0·08	−0·17±0·07
6	Cholic (12 g/l)	−0·15±0·06*	+0·03±0·03*
4	Glyco. (12 g/l)	−0·20±0·06*	+0·14±0·10*
6	Cheno. (11·5 g/l)	−1·45±0·31*	+1·46±0·22*

All the bile acids, at physiological concentrations and pressures, damaged the pancreatic duct. This suggests that bile may cause pancreatic disease not only by directly injuring the pancreatic cells, but by increasing their permeability to other substances. The latter mechanism may be the more important one.

64. Four-year results of prospective trial for duodenal ulcer (TVP *v.* HSV)

D. J. RAY and C. G. KOFFMAN (Introduced by J. B. ELDER), *Departments of Medicine and Surgery, Manchester Royal Infirmary and University Hospital of South Manchester*

One hundred and forty-three patients (116 males and 27 females) with duodenal ulcer have taken part in a randomized prospective trial of truncal vagotomy and pyloroplasty (TVP) and highly selective vagotomy (HSV) organized in three Manchester hospitals. Seventy-one patients underwent TVP and 72 had HSV. Preoperative and early postoperative data were recorded by the surgeon. Late follow-up data were recorded by a physician unaware of the operation performed. An earlier analysis of the results (Manchester Ulcer Trial Group, 1977) revealed no significant difference between the groups with regard to recurrent ulceration (TVP 2·7 per cent, HSV 8 per cent) and functional results.

One hundred and thirty patients (91 per cent) have now been followed up for 2½–5½ years (mean 4 years). There have been 5 proved recurrent ulcers following TVP (7·6 per cent) and 12 after HSV (18·4 per cent). Functional results were assessed by one physician according to a Visick scale and the two groups were found to be very similar.

	Visick grading			
	1 %	2 %	3 %	4 %
TVP ($n=65$)	38 (58·4)	15 (23·0)	3 (4·6)	9 (13·8)
HSV ($n=65$)	41 (63·0)	8 (12·3)	2 (3·0)	14 (21·5)

There was significantly more diarrhoea after TVP (14 per cent) than HSV (1·5 per cent) ($P<0·025$) but no significant difference with regard to dumping, heartburn and vomiting.

There has been an increase in the incidence of recurrent ulceration in both groups since last reported but this increase is greater in the HSV group.

MANCHESTER ULCER TRIAL GROUP (1977) Prospective randomized trial of vagotomy in uncomplicated duodenal ulceration. *Br. J. Surg.* **64**, 823.

65. The effect of HSV and of SV+P on the relationship between gastric emptying and oral glucose tolerance

R. BITTNER, H. G. BEGER, M. MEVES and B. WILLERT, *Department of Surgery, Klinikum Charlottenburg, Free University of Berlin, Spandauer Damm 130, D-1000 Berlin 19, West Germany*

It is well documented that vagotomy produces changes in the pattern of gastric emptying. However, there is little information comparing the relationship between gastric emptying and the configuration of the glucose tolerance curve. In addition there are no measurements of these two parameters in the early and late postoperative course after different types of vagotomy.

Two groups of patients were studied: group 1, patients with selective gastric vagotomy and Finney-pyloroplasty (SV+P; $n=20$; M 17; F 3; 39 yr (20–50); 65 kg (48–93); 173·5 cm (155–189)). Group 2, 19 patients with HSV (M 13, F 6; 38 yr (29–61); 65 kg (50–107); 172 cm (160–183)). In each patient 3 measurements were performed (preoperatively, 11 days (9–13) postoperatively, 3·9 months (3–24) postoperatively) of oral glucose tolerance and of the half-life of gastric emptying.

The data in the Table are given as median and range. For statistical analysis the tests of Wilcoxon and Mann–Whitney were employed.

	$T_{\frac{1}{2}}$ (min)	Blood glucose (mg/100 ml) Rate of rise (mg/min)	Peak
Group 1			
Preop.	52·5 (25–80)	1·89 (0·95–2·82)	123·6 (96·5–154·2)
Early p.o.	83 (47–370)	0·63 (0·45–2·47)	92·2 (64–170·5)
Late p.o.	46·5 (18–83)	2·66 (0·95–3·85)	126·7 (69–187)
Group 2			
Preop.	49 (28–74)	1·89 (0·93–4·15)	145 (82–200)
Early p.o.	102 (56–300)	0·36 (0·3–2·15)	89·2 (61–134)
Late p.o.	58 (25–195)	0·7 (0·25–2·5)	121 (35–174)

		Plasma insulin (u/l)	
	$T_{\frac{1}{2}}$ (min)	Fasting	Peak
Group 1			
Preop.	52·5 (25–80)	15·2 (7–28·5)	56 (21·5–175)
Early p.o.	83 (47–370)	14 (6–26.5)	22 (7·5–64)
Late p.o.	46·5 (18–83)	10 (2–64)	63·5 (20–345)
Group 2			
Preop.	49 (28–74)	11·5 (1·9–27.5)	58·7 (21–165)
Early p.o.	102 (56–300)	13·3 (6·5–35)	22 (5–54)
Late p.o.	58 (25–195)	15 (4–36)	45 (6–140)

Gastric emptying in the early postoperative period in both patient groups was significantly delayed ($P<0·01$). Glucose and insulin concentrations increased very slowly to a peak which showed only a small difference from the fasting value. In both groups the late postoperative $T_{\frac{1}{2}}$ returned towards normal. However, in the patients with SV+P the $T_{\frac{1}{2}}$ was shorter than preoperatively and was significantly shorter than in the patients with HSV ($P<0·05$). Corresponding with these results, in the SV+P patients the rate of rise of glucose concentration was greater than preoperatively and was also significantly more rapid than after HSV ($P<0·01$).

The results demonstrate that there is a close relationship between the pattern of gastric emptying and the configuration of the glucose tolerance curve. Thus the destroyed integrity of the antropyloric region in the patients with SV+P leads to both an uncontrolled gastric emptying and a precipitated increase of blood glucose concentration.

66. Distal intramural spread and local recurrence of rectal cancer

N. S. WILLIAMS, M. DIXON and D. JOHNSTON, *University Departments of Surgery and Pathology, The General Infirmary, Leeds*

With the advent of stapling instruments, and techniques such as transanal colo-anal anastomosis (Parks, 1972), it is technically feasible to perform sphincter-saving operations for most patients with low rectal carcinomas. If, however, the recommended 5-cm margin of distal clearance is adhered to, many of these patients will require permanent colostomies. We have therefore re-examined the relevance of the 5-cm rule.

Fifty consecutive abdominoperineal resection specimens were examined by multiple sections distal to the tumour. All lesions were situated 5–10 cm from the anal verge on sigmoidoscopy. Only 3 specimens (6 per cent) showed distal intramural spread of less than 1 cm. All 3 were poorly differentiated Dukes' C tumours.

All anterior resections performed between 1957 and 1968 were reviewed. The minimum period of follow-up was 10 years. In 82 curative operations, 32 (group 1) were resected with a distal margin greater than 5 cm (mean 7 cm) and 50 (group 2) with a margin less than 5 cm (mean 2·6 cm). The age and sex distribution was similar in both groups. Local recurrence was found in 3 patients (9·3 per cent) in group 1 (all had poorly differentiated lesions) and in 8 patients (16 per cent) in group 2 (7 poorly differentiated, 1 well differentiated). Of the 11 patients with recurrence, 9 had Dukes' C growths.

Thus a 5-cm margin of clearance is needed only in patients who have poorly differentiated tumours, most of whom are incurable because of other modes of spread.

67. Hepatoprotection by inosine and chlorpromazine from *in vivo* normothermic liver ischaemia assessed by orthotopic rat liver transplantation

D. B. JACKSON and K. E. F. HOBBS, *Academic Department of Surgery, Royal Free Hospital, London*

Orthotopic rat liver transplantation as a model for evaluation of liver preservation methods has been described (Jackson and Hobbs, 1977). This model has now been used to assess the ability of the purine nucleoside inosine and the drug chlorpromazine to protect the rat liver from 60 min *in vivo* normothermic ischaemia; an otherwise fatal ischaemic insult when assessed by subsequent orthotopic transplantation.

Inosine can protect rat kidneys from *in vivo* warm ischaemia (Fernando, 1976) but has no effect when renal preservation is evaluated using the isolated perfused rat kidney (Marshall et al., 1978). Chlorpromazine is an established hepatoprotectant preventing lobar ischaemic liver cell death *in vivo* (Chien, 1977).

Group	No.	*In vivo* donor ischaemia	Protectant	Survival
1	10	0–1 min	—	8
2	10	60 min	—	0
3	8	60 min	I.v. inosine	3
4	8	60 min	I.v. chlorpromazine	4
5	8	60 min	Regional hypothermia 25–30 °C	2

Hepatoprotection was obtained by inosine, chlorpromazine and regional hypothermia.

68. Studies in renal preservation using the isolated perfused rat kidney: evaluation of citrate flushing solution

PAULA JABLONSKI, B. HOWDEN, V. MARSHALL, D. SCOTT and A. KUNCIUNAS, *Monash University Department of Surgery, Prince Henry's Hospital, Melbourne, Australia*

Evaluation of renal preservation is conventionally by reimplantation of the stored canine kidney which has attendant limitations—survival is influenced by technical, anaesthetic and after-care factors. The isolated perfused rat kidney model allows rapid and economical screening of preservation methods. A standardized system provides early and repeated evaluation of organ function from serial analysis of perfusate, urine and tissue. Criteria used are urinary/plasma inulin ratio, glomerular filtrate rate, sodium and potassium reabsorption and excretion, tissue adenine nucleotide content and histology.

The validity of the model has been demonstrated by correlation of functional parameters and of adenine nucleotide content with increasing periods of prior warm and cold ischaemia. For cold flush-ice preservation of the kidney, a hyperosmolar (400 mosmol/l) solution containing citrate (HC) was demonstrated to be superior to alternative flushing solutions (Collins', Sacks' and Perfudex).

Further investigation of the effective components of the HC solution has been made by adjusting the mannitol concentration to give solutions of varying osmolality (300, 350 and 400 mosmol/l) with a constant citrate content. After cold flush with the test solutions and 24 hours' ice storage, renal function was significantly ($P<0{\cdot}01$) better maintained by the three citrate solutions than with Hartmann's solution in each case. The isomolar citrate solution gave significantly better renal function than the hyperosmolar (400 mosmol/l) solution ($P<0{\cdot}05$). Of the functional parameters tested sodium reabsorption appeared the most senstive index.

Our findings suggest that the efficacy of the HC solution in kidney preservation is due not to hyperosmolality but to specific effects of citrate and/or other components.

69. Improvement of hypothermic kidney storage preservation by using sub-zero temperatures

R. GRUNDMANN, G. BROMBERGER, D. HELLING and H. PICHELMAIER, *Chirurgische Universitätsklinik Köln-Lindenthal, Joseph-Stelzmann-Str. 9, 5000 Köln 41, Germany*

The main principle of hypothermic kidney storage preservation is based on the reduction of metabolism by hypothermia. Temperatures of +2 to +4 °C are applied in clinical practice today. Theoretically, the results should become even better if metabolism is further reduced by temperatures below 0 °C. This was tried in the experiments presented here.

Bilateral nephrectomy was performed in mongrel dogs of 20–25 kg body weight. The kidneys were flushed with 500 ml of Collins' C_3-solution which contained 120 g/l saccharose (035M) and then stored in this solution for 12 ($n=8$) and 24 h ($n=7$) at −2 °C. The osmolality of the solution ranged about 770 mosmol/kg. The Na^+ concentration was 9 mmol/l, the K^+ concentration was 104 mmol/l. The temperature was controlled continuously with puncture electrodes in the medulla of the kidney to about −2 °C. The control group was stored in Collins' or Sacks' solution at +4 °C. After storage the kidneys were transplanted to the neck vessels of a recipient animal and the immediate function of the kidneys was assessed for 6 h with PAH and inulin clearances.

	Hypertonic solution at −2 °C	Control groups at +4 °C	
		Collins'	Sacks'
2 h storage:			
PAH (ml min^{-1} 100 g^{-1})	$50{\cdot}1\pm21{\cdot}1$	$50{\cdot}0\pm14{\cdot}9$	$61{\cdot}0\pm17{\cdot}4$
Inulin (ml min^{-1} 100 g^{-1})	$13{\cdot}4\pm5{\cdot}5$	$8{\cdot}3\pm3{\cdot}6$	$10{\cdot}4\pm5{\cdot}8$
	($n=8$)	($n=6$)	($n=6$)
24 h storage:			
PAH (ml min^{-1} 100 g^{-1})	$35{\cdot}9\pm19{\cdot}4$	$14{\cdot}2\pm9{\cdot}3$	$11{\cdot}4\pm13{\cdot}5$
Inulin (ml min^{-1} 100 g^{-1})	$13{\cdot}2\pm7{\cdot}1$	$2{\cdot}9\pm2{\cdot}0$	$2{\cdot}5\pm1{\cdot}9$
	($n=7$)	($n=6$)	($n=6$)

Dog kidneys can be stored successfully for 24 h in an intracellular solution at 770 mosmol/kg. If this solution is used, the kidneys do not freeze at −2 °C. Kidneys work significantly better after 24 h storage if they are stored in a hypertonic solution such as Collins' or Sacks' at −2 °C. This means that kidney metabolism can be really reduced by decreasing the temperature below 0 °C, and therefore kidneys function better after transplantation. The prerequisite for the success of this method is the use of a highly hyperosmolar solution.

70. Relevance of HLA matching and HLA-A2 to outcome in cadaveric renal transplants

A. G. BIRTCH, P. R. MCCONNACHIE and W. T. FINCH, *Section of Transplantation, Southern Illinois School of Medicine and Memorial Medical Center, Springfield, Illinois, USA*

Controversy continues in the United States concerning benefits of human lymphocyte antigen (HLA) matching and the matching of any one HLA Ag in cadaver renal transplantation (Opelz, 1977). HLA-A2 matching was described as a factor in avoiding sensitization to platelet transfusions (Duquesnoy et al., 1977).

We report 64 consecutive cadaver renal transplants (January 1973–December 1978) in which HLA matching correlated strongly with kidney functional survival and matching for the common HLA-A2 Ag significantly reduced rejection loss.

Matching for 2 or more HLA Ags improved functional survival at each time interval: 6 month 39/49 *v.* 6/11; 1 year 34/42 *v.* 5/11; 2 year 20/28 *v.* 3/11; and 3 year 13/18 *v.* 1/9 ($P<0{\cdot}05$, $P<0{\cdot}01$ Fisher's exact test). This effect is most prominent in the low risk group (<45 years) where 2 to 4 Ag-matched kidneys function at 90 per cent at 1 year (28/31), 89 per cent at 2 years (17/17) and 86 per cent at 3 years (12/14).

HLA-A2 Ag-matched transplants had a lower incidence of rejection episodes during the first month (66·7 per cent *v.* 90·3 per cent χ^2 ($P<0{\cdot}05$) and a decreased cumulative rejection loss from 3/8 in HLA-A2 mismatch and 7/23 in non-HLA-A2 matches to 2/33 in the HLA-A2-matched patients ($P<0{\cdot}05$ Fisher's exact test). None of the 2 to 4 Ag-matched HLA-A2-matched patients has rejected their graft (0/30).

We conclude that for an increased chance of successful transplantation, two or more antigens should be matched in cadaver transplants and that if the recipient has HLA-A2 this antigen should be matched.

OPELZ G. (1977) Histocompatibility testing in renal transplantation. *Urology* (Suppl.) **9**, 72–81.

71. Histocompatibility matching and renal allograft survival in dogs

A. B. BIJNEN, H. OBERTOP, H. M. VRIESENDORP and D. L. WESTBROEK, *Laboratory for Experimental Surgery, Erasmus University, Rotterdam, The Netherlands*

With the present methods of histocompatibility matching an excellent correlation of matchgrade with human kidney allograft survival is seen in related donor-recipient pairs (DRP) but this correlation is much less clear in cadaver kidney transplantation. Experimental animal models may be helpful to clarify this discrepancy and to develop better methods for donor selection. Histocompatibility matching in dogs is performed in our laboratory by the use of serologic tests and mixed lymphocyte cultures to detect the serologically defined (SD) and lymphocyte defined (LD) antigens respectively. The genetic code for these antigens is carried by a chromosomal region called the major histocompatibility complex (MHC). Over one hundred kidneys were transplanted to test the efficacy of matching for these antigens under varying defined conditions. In some protocols standard immunosuppression was used (2 mg Imuran and 1 mg prednisolone kg BW^{-1} d^{-1}). Kidney function was considered to have ceased when serum creatinine exceeded 1000 µmol/l; histological examination of the graft was always performed.

Analysis of the data shows that better matching for SD and/or LD antigens is correlated with improved kidney allograft survival in littermate DRP, but much less so in nonlittermate DRP. In unrelated mongrels, LD, but not SD matching improves kidney allograft survival. The data obtained in immunosuppressed dogs suggest that undefined 'minor' (non-MHC) antigens are comparable in strength with the SD and LD antigens, SD+LD typing appears to have a better effect if the recipient is treated with immunosuppressive drugs. Thus histocompatibility matching and immunosuppression appear to be synergistic. Administration of third party blood transfusions prior to transplantation may also enhance renal allograft survival in immunosuppressed dogs, but it remains to be seen whether histocompatibility matching and blood transfusions have a synergistic effect too.

72. Comparison of physiological events, high energy phosphate content and mitochondrial function during ischaemia in normal and hypertrophied hearts

J. D. SINK, W. D. CURRIE, R. C. HILL, G. L. PELLOM, C. O. OLSEN, R. N. JONES and A. S. WECHSLER, *Departments of Surgery, Duke University Medical Center, and Durham Veterans Administration Medical Center, Durham, North Carolina, USA*

Although hypertrophied myocardium appears more susceptible to ischaemic injury during cardiac operations than non-hypertrophied myocardium, the biochemical response of hypertrophied hearts to ischaemia has not been fully elucidated. High energy phosphate levels (ATP, CP μmol/g dry weight) and mitochondrial function were determined in 75 normal and 103 hypertrophied isolated rat hearts following 15 min of Langendorf perfusion (control) at initiation of ischaemic contracture and at completion of ischaemic contracture.

Hypertrophy, produced by banding the ascending aorta 6 weeks before study, was confirmed by left ventricular (mg/g body weight) ratios (normal 1·92 wet, 0 43 dry; hypertrophy 2·69 wet, 0·59 dry). Qo_2 (nanoatoms oxygen min^{-1} mg protein^{-1}), ATP : O and respiratory control index (RCI) were calculated from isolated mitochondria polarographically. Results (mean±s.e. mean) with NAD-linked substrate are shown in next column and were similar for FAD-linked substrate.

Although ATP and CP content was consistently lower in hypertrophied hearts, mitochondria from hypertrophied hearts demonstrated significantly ($P<0·05$) higher active respiration (Qo_2) and respiratory control (RCI). Contracture initiation occurred sooner with hypertrophy but completion was delayed. These results suggest that the increased susceptibility of hypertrophied myocardium to ischaemic contracture may be due to the lower ATP stores present with the onset of ischaemia.

	Control N	 H	Contracture initiation N	 H
Qo_2	97·1±8·5	134·0±10·2	94·4±9 8	149·8±20·2

73. Pharmacological analysis of the mesenteric vasodilator effect of vasoactive intestinal peptide (VIP)

J. KACHELHOFFER, J. MARESCAUX, P. SAVA and J. F. GRENIER, *Inserm U 61, Chirurgie Expérimentale et Physiopathologie Digestive, 67200 Strasbourg Hautepierre, France*

Among a broad spectrum of biological activities, VIP has been shown to be a vasodilator of the intestinal vascular bed. The purpose of the present study was to analyse the mode of action of this polypeptide on the mesenteric blood vessels using a pharmacological approach.

The investigations were carried out on isolated canine jejunal loops perfused at normothermia, under pulsatile flow, with heparinized and oxygenated blood. The vascular effects were studied by analysing the changes of the vascular resistance produced by VIP (500 μg/l ≃ED$_{50}$) before and during blockage or inhibition of the β-adrenergic receptors by propranolol (5–10 mg/l of blood), the cholinergic receptors by atropine (5–10 mg/l), the dopaminergic receptors by haloperidol (10 mg/l), the prostaglandins synthesis by indomethacin (5–10 mg/l) and also during infusion of tetrodotoxin (TTx—0·25 mg/l). Except for indomethacin and TTx, the efficacy of each antagonist was tested by analysing its blocking action on the vasomotor effect of a specific agonist.

Results: 1. Propranolol inhibits 29 per cent (±7 per cent) of the vascular effects of VIP whereas at the same blood concentration it antagonizes in a proportion of 71 per cent (±9 per cent) the vasodilatation induced by isoprenaline. 2. Atropine, at concentrations which suppress 96 per cent (±6 per cent) of the vascular effect of acetylcholine, inhibits the VIP induced vasodilatation only in a ratio of 29 per cent (±8 per cent). 3. Haloperidol antagonizes the vascular effect of VIP in a proportion of 32 per cent (±5 per cent) whereas this blocking agent suppresses 53 per cent (±4 per cent) of the vasodilatation induced by dopamine. 4. Indomethacin and TTx have no effect on the vasodilator properties of VIP.

These results suggest that neither the classic nervous pathways nor the mediation by vasodilator prostaglandins intervene in the mesenteric vasodilatation produced by VIP. The partial inhibition observed in the presence of several blocking agents used may result from non-specific effects of the antagonists. The absence of any inhibitory action of TTx is not conflicting with the neurotransmitter hypothesis recently proposed for VIP, in so far as the vascular effects of this polypeptide observed in the present study correspond to a receptor stimulation of exogenous nature. All these data argue for the existence of a specific receptor for VIP at the level of the mesenteric vascular smooth muscle.

74. An investigation into the maximum activities of four key enzymes in the muscle of malnourished patients with cancer or benign disease

R. F. G. J. KING, J. MACFIE, T. J. GÖNYE and G. L. HILL, *University Department of Surgery, The General Infirmary, Leeds*

There is a depression of key enzymes controlling glucose and glycogen breakdown in the muscle of malnourished patients with cancer (Lundholm et al., 1978). It has been suggested that this is due to a specific action of the tumour but it is not known if it also occurs in malnourished patients without cancer.

We have studied the maximum activities (MA) of four key enzymes of glucose oxidation in skeletal muscle obtained from 11 patients with cancer (mean age 68±3·3 years and mean weight loss 15·8±2·0 per cent) and from 10 with benign disease (mean age 59±4·9 years and mean weight loss 19·9±2·3 per cent). In small samples of rectus muscle, measurements were made of α-ketoglutarate dehydrogenase (α kg) an an indicator of the MA of the Krebs cycle, phosphofructokinase (PFK) for glycolysis, fructose 1·6-diphosphatase (F16DP) for substrate cycling in the fructose 6 phosphate-fructose 1·6-diphosphate couple and hexokinase (HK) as an indicator of the MA at which glucose can be channelled into hexosephosphates of the glycolytic pathway.

	HK*	PFK*	F16DP*	α kg*
Cancer	0·89±0·23	29·8±1·72	0·61±0·12	0·10±0·03
Benign disease	1·14±0·13	30·9±2·6	0·78±0·2	0·09±0·02
P	n.s.	n.s.	n.s.	n.s.

All results expressed as mean±s.e. mean.

*MA as μmol min⁻¹ g muscle⁻¹.

These results show that the MA of Krebs cycle, glycolysis, glucose mobilization and the sensitivity to glucose utilization by the substrate cycle PFK/F16DP is similar in both patient groups. The steady-state levels of the enzymes we have measured are less than published control values and are more likely to be the consequence of malnutrition rather than a specific action of the tumour.

75. Reduction of operative morbidity and mortality by combined preoperative and postoperative nutritional support

J. L. MULLEN, G. P. BUZBY, D. C. MATTHEWS, B. F. SMALE and E. F. ROSATO *Nutrition Support Service, Hospital of the University of Pennsylvania, Philadelphia, USA*

Reduction of operative morbidity and mortality by preoperative nutritional support (TPN) has never been adequately demonstrated. To determine if preoperative nutritional assessment can identify patients at increased risk of subsequent nutritionally based complications, and to determine if preoperative TPN decreases morbidity and mortality in this high-risk group, 306 elective surgical patients underwent nutritional assessment on admission including albumin (ALB), transferrin (TFN), total protein, mid-arm muscle circumference, triceps skinfold (TSF), lymphocyte count, delayed hypersensitivity reactivity (DH), weight and weight loss history. The patient's clinical course was monitored until death or discharge. Based on the first 161 patients, computerized discriminant analysis identified parameters predicting morbidity and mortality and a linear predictive model was developed.

Predicted risk (%) = 158−16·6 (ALB)−0·78 (TSF)−0·2 (TFN)−5·8 (DH).

To test for predictive accuracy and clinical applicability, and to determine the efficacy of TPN in decreasing morbidity and mortality in the high risk group, the model was applied prospectively to two groups of patients undergoing major elective surgery to permit comparison of actual and predicted outcome (group 1, patients receiving no preoperative TPN; gruop 2, patients receiving pre- and postoperative TPN).

	Low (<40%)	Int. (40–49)	High (>49)	*P*< (χ^2)	*P*< high risk†

† TPN *v*. No. TPN.

The first step in rational nutritional management is nutritional assessment to identify the high risk patient. This clinically applicable model provides an index of nutritional status which accurately and prospectively identifies patients at increased risk of operative morbidity and mortality. In this high risk group, combined with pre- and postoperative nutritional support reduces operative morbidity ($P<0·01$) and mortality ($P<0·01$).

76. Metabolic homeostasis during liver transplantation in the pig

E. HERRERA, J. SOLSONA and R. CAMPRODON, *Unidad Cirugia Experimental, Ciudad Sanitaria 'F. Franco', Barcelona, and Departamento Investigación Centro 'Ramon y Cajal', Madrid, Spain*

Hepatectomy followed by orthotopic liver transplantation in the pig has been used in the present work as an experimental model to study the role of the liver in the control of metabolic homeostasis.

Ten 24-h fasted pigs were totally hepatectomized and homologous livers from 24-h fasted donors were transplanted orthotopically with a preservation time of less than 60 min. Sham operated animals were used as controls. Liver biopsies were rapidly placed in liquid nitrogen for glycogen analysis and blood samples were collected from the external jugular vein at different times during the operation. Glucose and glycerol were evaluated in plasma by enzymatic methods, free-fatty acids by a colorimetric method and individual amino acids by using a 121-MP Beckman autoanalyser with nor-leucine as internal standard.

Glycogen concentration decreased in the donor's liver during the preservation period and after the transplant. Plasma levels of glucose, alanine, ornithine, taurine, glycerol and free fatty acids increase while the levels of glutamate decrease and those of arginine completely disappear during the 'ahepatic phase'. Up to the thirtieth minute after the end-to-end portal anastomosis, blood glucose levels were decreased compared with controls, while the values of glycerol, free fatty acids and glutamate were normal, the other amino acids being maintained at the same level as during the 'ahepatic phase'.

The glucose production from extrahepatic organs supported by the release of amino acids from the muscles and the utilization of lipid stores maintain glucose homeostasis during the 'ahepatic phase'. The length of time the transplanted liver takes to get over its biosynthetic activity in the presence of its rapid consumption of metabolic fuels endangers the survival of the animal and indicates exogenous perfusion of substrates.

77. Studies of peritoneal phagocytes as therapy for faecal peritonitis

L. M. FLINT JUN., J. H. CALHOUN, M. D. ANDERSON and J. D. RICHARDSON, *Department of Surgery, University of Louisville School of Medicine, Louisville, Kentucky, USA*

Peritonitis remains a leading cause of postoperative death despite operation and antibiotics. Interest in natural defences led to this study of intraperitoneal phagocytes (Pph) as specific therapy for established bacterial peritonitis.

Peritoneal phagocytes were harvested from Sprague–Dawley rats 72 h after stimulation with i.p. zymosan. Viable cells were subjected to differential counting and phagocytic activity assessed by chemiluminescence. Pph in a ratio of 10 cells/bacterium were injected i.p. in rats 2 h after an LD_{90} i.p. dose of sterile human faeces and *Escherichia coli*. Controls received equal volumes of saline i.p. *In vitro* studies of bacterial inactivation by Pph were also performed. Pph (10^7 cells) were incubated for 4 h with 10^8 *E. coli* in each of four solutions: (A) Pph+*E. coli*+saline; (B) Pph+*E. coli*+2 per cent haemoglobin (HGB); (C) Pph+*E. coli*+sterile faeces; (D) Pph+*E. coli*+peritoneal exudate. Because HGB is an inhibitor of phagocytosis, solution B was used as an *in vitro* model of impaired bacterial inactivation. Solution C was prepared from autoclaved faeces. Solution D was a cell and bacteria-free filtrate of peritoneal fluid from rats dying of peritonitis. Twenty-four hour mortality rates were recorded for *in vivo* studies. Quantitative cultures obtained before and after incubation allowed expression of bacterial inactivation *in vitro* as a percentage of original concentration.

$$\left(1-\frac{\text{Org/ml after incubation}}{\text{Org/ml before incubation}}\times 100\right).$$

Eleven of 12 (92 per cent) control rats died as did 10 of 12 treated rats (83 per cent). *In vitro* inactivation data are shown:

	% inactivation			
Solution	A	B	C	D
2 h	60	60	0*	0*
4 h	90	60	0*	0*

*$P = 0·05$ compared to solution A.

Factors are present in sterile faeces and filtered peritoneal exudate which prevent bacterial inactivation by Pph, and apparently preclude improved survival by this method.

78. Can intravenous fat emulsions be justified as a non-protein calorie source?—a controlled clinical trial

J. MACFIE, R. C. SMITH, C. K. YEUNG and G. L. HILL, *University Department of Surgery, The General Infirmary, Leeds*

The cost per calorie of intravenous fat is 10–20 times greater than hypertonic dextrose. The advantages of fat emulsions must therefore be unequivocal before their routine use as a non-protein calorie source (NPCS) can be recommended.

We have studied 22 critically ill surgical patients who required intravenous nutrition (IVN). They were matched for age, sex, pre-illness weight, weight loss and diagnosis and allocated to two treatment groups: group 1 (6F, 5M; 60±14 years) received 50 per cent dextrose as the NPCS (mean calorie intake; 50±9 kcal kg^{-1} d^{-1}) and group 2 (7F, 4M; 61±19 years) 60 per cent of their NPCS as fat and 40 per cent as dextrose (56±11 kcal kg^{-1} d^{-1}). Both groups received an 8·5 per cent crystalline amino acid solution providing a calorie to nitrogen ratio of 150 : 1. The changes in body weight, fat, protein and water over the 2 week study period were calculated by the method of Hill et al. (1978). Plasma proteins and liver function tests were also measured.

The results for the groups were as follows:

	Group 1	Group 2
ΔWeight (kg)	2·2±0·8*	2·4±0·7**
ΔFat (kg)	0·9±0·3*	0·3±0·3
ΔProtein (kg)	0·1±0·3	0·3±0·2
ΔWater (kg)	1·3±0·9	1·7±0·7*
ΔAlbumin (gl/)	−0·45±0·4	1·1±0·3
ΔGOT (i.u./l)	13·1±2·3	2·8±1·1

All results expressed as mean±s.e. mean.

* Significant at 5 per cent level by paired *t* test.

** Significant at 1 per cent level.

None of the changes in group 1 is significantly different from those in group 2 (non-paired *t* test) except the plasma GOT ($P<0·01$) where the magnitude of the change is unlikely to be of clinical importance. We conclude that the routine use of fat emulsions as a NPCS is not justified on the basis of cost.

HILL G. L., MCCARTHY I. D., COLLINS J. P. et al. (1978) A new method for the rapid measurement of body composition in critically ill surgical patients. *Br. J. Surg.* 64, 723–735.

79. Tissue perfusion in extracorporeal circulation using bubble or membrane oxygenators

R. L. PRANGER, J. M. ELSTRODT, P. H. MOOK, M. KESSLER, D. W. LUBBERS and CH. R. H. WILDEVUUR, *Max-Planck-Institute of Physiology, Dortmund, W. Germany and Department of Experimental Surgery, University Hospital, Groningen, The Netherlands*

Improvements in blood compatibility and microcirculation have been claimed by using membrane oxygenators (MO) instead of bubble oxygenators (BO) in open heart surgery. These mainly clinical impressions have not been substantiated, with regard to tissue perfusion. Using Po_2 histograms muscle perfusion in dogs undergoing ECC (2 h) was studied with BO ($n=8$) or MO ($n=7$). Po_2 was measured with a P_2-multiwire ($n=8$) surface electrode. The frequency distribution of 104 Po_2 values was recorded and graphically plotted by a computer program which represents one histogram. These histograms were measured before operation (H_1), after cannulation for total bypass was performed (H_2), immediately after partial bypass (H_3), during 1 hour's (H_4) and 2 hours' (H_5) perfusion and 1 h after perfusion (H_6).

Haematological studies including platelet numbers and function (ADP-induced aggregation) were performed. The circuit was primed with about 1·0 l of homologous blood. After precirculation (10 min) of the dog (400 ml/min) an initial fall in platelet numbers and function was measured and this coincided with a severe impairment of H_3 while arterial pressures frequently showed an initial rise often followed by a severe pressure drop. The continuously monitored muscle surface Po_2 dropped to zero. A severe shunting phenomenon is apparently the initial reaction following the first blood contact with foreign material. During perfusion the histograms (H_4 and H_5) remained acceptable in both groups and were mainly dependent on the perfusion pressures. After ECC a clear differentiation appeared between the BO and the MO groups. In the BO group severely impaired histograms (H_6) were observed correlating with higher systemic vascular resistance (SVR) and decreased platelet numbers and function. In contrast, the MO group had normal histograms (H_6), low SVR and better maintained platelet numbers and function.

In this study improvements of MO compared to BO could be quantitated in regard to better tissue perfusion after ECC which correlated with a better haemocompatibility. Po_2 muscle surface histograms appeared to be a reliable method to evaluate tissue perfusion objectively and substantiate the clinical observation that patients after MO perfusion have a better peripheral circulation than patients after BO perfusion.

80. Induction of pulmonary dysfunction by fragment D: platelet aggregation

DIANA MAINWARING and P. W. CURRERI, *Department of Surgery, Cornell Medical Center, New York City, USA*

The plasma concentration of fibrinogen degradation product D (FDP-D) is markedly increased following burn or trauma. Purified human FDP-D infused into awake, restrained, untraumatized rabbits (100 μg/ml blood) causes progressive thrombocytopenia, pulmonary dysfunction, vascular leak and interstitial neutrophilia (Luterman et al., 1977). Rabbits treated with diphenhydramine (Benadryl) prior to FDP-D infusion fail to develop this pathology (Mainwaring et al., 1978).

This study examined platelet aggregation, ATP release and prostaglandin synthesis in rabbits receiving FDP-D (group 1, $n=4$) alone or FDP-D following diphenhydramine pretreatment (group 2, $n=4$). Platelet-rich plasma (PRP) was prepared from citrated blood drawn via a femoral arterial catheter at 0, 1, 2½ and 4 h post infusion. Platelet aggregation was stimulated with either collagen or ADP. Malonaldehyde (MDA), a byproduct of prostaglandin synthesis, was measured by colorimetry. Animals were sacrificed at 4 h.

	Group 1		Group 2	
	0 h	4 h	0 h	4 h

* $P<0\ 005$; ** $P<0·01$; † $P<0·05$; †† $<0·002$; change from time 0.

Aggregation and release were enhanced in FDP-D PRP since all response times shortened. Total ATP and MDA release increased. Diphenhydramine pretreatment inhibited FDP-D simulated aggregation, ATP release and prostaglandin synthesis. No pretreated animal had thrombocytopenia or respiratory distress. Enhancement of platelet aggregation and release represents one mechanism by which FDP-D induces pulmonary dysfunction. Diphenhydramine inhibits these responses and may prove therapeutic in post-traumatic pulmonary complications.

81. Clinical comparison of haemostasis in membrane and bubble oxygenator perfusion

J. J. A. M. VAN DEN DUNGEN, G. F. KARLICZEK, J. N. HOMAN VAN DER HEIDE and CH. R. H. WILDEVUUR, *Department of Experimental Surgery and Department of Thoracic Surgery, University Hospital, Oostersingel 59, 5700 RB Groningen, The Netherlands*

Most clinical evaluations of bubble oxygenators (BO) compared to membrane oxygenators (MO) report no or only minor differences in postoperative blood transfusion requirements. However, other facts like cardiotomy suction might obscure important differences, especially when no sensitive indices like platelet function are measured.

In this clinical study of 40 strictly comparable coronary artery bypass operations the Travenol TMO was used in 21 patients and the Polystan VT 5000 in 19 patients. In the TMO group platelet function was better maintained (>35 per cent) as compared to the VT group during the period of aortic crossclamping, but decreased rapidly when intensive cardiotomy suction started. After protamine administration a further impairment of platelet function was seen. Consequently, after perfusion the functions in the TMO group were the same as the VT group, which was already impaired shortly after the onset of perfusion. During the VT perfusion platelet numbers were more affected ($P<0·02$) compared to the numbers during TMO perfusion. There were no significant differences in erythrocyte number, plasma haemoglobin, postoperative blood loss or blood transfusion requirements in the two groups.

In conclusion, no difference in haemostasis could be measured after BO and MO perfusion. However, the haematological data during perfusion showed that improvements by TMO perfusion were obtained, but were counteracted by cardiotomy suction and protamine administration. After perfusion equal levels of platelet numbers and function were measured in both groups which substantiate the common finding of equal haemostasis in BO and MO perfusion. Improvements in haemostasis with MO perfusion are only to be expected when the damage by suction and protamine administration can be controlled.

82. The effect of ischaemic arrest on the compliance of the canine left ventricle measured by changes in regional passive elastic stiffness

C. A. S. MARRIN, D. J. ARENA, J. G. NAPOLI, J. MEISNER and H. M. SPOTNITZ, *Department of Surgery, Columbia University College of Physicians and Surgeons, New York, USA*

Detection of changes in left ventricle (LV) compliance may prevent irreversible ischaemic injury during cardiac surgery.

We developed a gauge to measure passive elastic stiffness (PES) of myocardium in intact, arrested left ventricles (LV). A miniature hydraulic system stretched a segment of myocardium up to 140 per cent of initial length while recording the pressure developed within the system. Serial force-length (FL) curves were recorded for 15 excised LV during the onset of rigor.

Myocardial PES was measured for the left ventricular free wall and for the interventricular septum in two orientations—parallel to (longitudinal) and perpendicular to (circumferential) the long axis of the LV. Serial pressure-volume (PV) curves were recorded as an index of global compliance.

Exponential curves were fitted to the digitized FL and PV curves by computer. Analysis of variance revealed no significant difference in PES between free wall and septum. Percentage extension produced by a given force decreased as a function of time on both orientations, paralleling the changes in the PV curves ($P<0·001$). Although there was no significant difference between longitudinal and circumferential PES measured initially ($P<0·5$), longitudinal was significantly greater than circumferential PES at rigor ($P<0·001$).

We conclude that changes in regional PES of myocardium can be used to monitor ischaemic changes in global LV compliance.

83. Surgical application of an artificial pancreas

L. LAMBOTTE, M. REYNAERT, J. B. OTTE, D. MOULIN, B. GRIBOMONT, J. RAHIE, A. E. LAMBERT, M. BUYSSCHAERT and P. J. KESTENS, *Laboratory of Experimental Surgery, UCL 5570, 1200 Brussels, Belgium*

The artificial pancreas (AP)—insulin and glucose administration under computer control—has usually been applied in the medical emergency (e.g. diabetic coma) and in order to establish the insulin requirement of unstable diabetic patients. We present two new applications of the AP to surgical patients.

Hyperinsulinism: Continuous recording of blood glucose level during a fasting period is an established procedure in the diagnosis of insulinoma. With AP this information can be quantified by the determination of the amount of glucose needed to maintain a normal glucose level and thus performing the test without the risks inherent to hypoglycaemia. In a 30-year-old male, AP was connected before and during surgical removal of a pancreatic tumour and it reduced within minutes of removal of the tumour the need for exogenous glucose, clearly indicating that only one insulinoma was involved and had been removed. The artificial pancreas was also connected to a 10-month-old girl who had suffered from birth frequent attacks of severe hypoglycaemia. These symptoms were attributed to nesidioblastosis, a diffuse hyperplasia and ectopic localization within the pancreas of the endocrine tissue. This girl required continuous glucose administration (3–6 g/h) to maintain normoglycaemia. A 75 per cent pancreatectomy was performed with no reduction in the amount of glucose administered over the next 24 h (3·3±0·1 g/h). A second operation was then performed leading to a 90 per cent pancreatectomy. Exogenous glucose was no longer needed and 3 months later the child maintains normoglycaemia. The diagnosis of nesidioblastosis was confirmed histologically.

Total parenteral nutrition: AP was applied to total parenteral nutrition in 7 totally or partially pancreatectomized patients mainly during and after acute episodes of sepsis. When these patients were connected to the AP the blood glucose level was maintained strictly in the normal range even with increasing administration of glucose.

In conclusion, AP has been found to be a reliable method of maintaining normoglycaemia over prolonged periods with minimal medical supervision.

84. A simplified procedure of canine pancreatic tissue preparation for intrasplenic autotransplantation

V. MIRKOVITCH, M. CAMPICHE, B. WINISTÖRFER, F. MOSIMANN and R. MACARONE-PALMIERI, *Experimental Surgery, University Surgical Services, CHUV, 1011 Lausanne, Switzerland*

Under pentobarbital anaesthesia and aseptic conditions, the horizontal part of a dog pancreas was removed, its volume measured and subsequently placed in a Petri dish and infiltrated with a solution of collagenase (2000 U/ml; type 1 Sigma Chemical Co., St Louis, Mo.). Three ml of this solution were employed to infiltrate 1 ml of pancreatic tissue. After complete infiltration, the swollen gland was cut by hand with a scalpel in the same Petri dish into 2–4 mm particles. The entire contents of the Petri dish were then carefully transferred into a beaker and rinsed with 1 l of Ringer's lactate solution pre-heated to 37 °C (1 mM $NaHCO_3$ added to raise pH to 7·50). The contents of the beaker were allowed to sediment for 5 min. The supernatant was removed and additional rinsing and sedimentation were performed, after which the sedimented tissue was transferred to a syringe and autotransplanted into the animal's spleen. The surgical procedure was terminated with the removal of the remaining pancreatic tissue. Postoperatively, the dog received no antidiabetic treatment. Of the 14 dogs so studied, 13 animals became spontaneously normoglycaemic; this normoglycaemia persisted for many months and in one case, up to 2 years. Postoperative glucose-loading tests gave values that were not significantly different when compared with those obtained from control animals. Concurrently, plasma insulin levels rose promptly to values not significantly lower than in non-operated dogs. Histological examination of the spleens of normoglycaemic animals confirmed the existence of multiple foci of endocrine and exocrine tissue of normal appearance.

85. Function of an ectopic liver recomposed from transplanted hepatocytes in the spleen

M. MITO, H. EBATA, M. KUSANO, T. OHNISHI and T. SAITO, *Second Department of Surgery, Asahikawa Medical College, Nishikagura, 4–5, Asahikawa, Hokkaido, 078–11, Japan*

Based on the similarity displayed by transplanted isolated hepatocytes in the spleen with normal hepatic architecture, an ectopic liver was examined for biological functions.

Twenty inbred adult Wistar rats in which isolated hepatocytes were transplanted in their spleens 1 year previously were used.

1. Histochemical (periodic acid-Schiff and G-6-Pase stains) and immunofluorescent (albumin) studies and α-fetoprotein (AFP) measurements were performed.

2. Six out of 20 rats underwent portacaval shunt (PC shunt) and subsequently, at 3–4 weeks, Indocyanine Green (ICG) clearance (0·5 mg/100 g BW) and ammonia tolerance (0·05 ml of 2·14 per cent NH_ACl/100 g BW) tests were done. In the ammonia tolerance test, the hepatic artery was ligated immediately after NH_4Cl injection in order to detect the isolated function of the ectopic liver from the host liver. Six normal rats with PC shunt but without transplantation were taken as a control.

1. Periodic acid-Schiff stain revealed generous glycogen granules in the cytoplasm of transplanted hepatocytes and G-6-Pase stain specifically demonstrated cellular viability.

2. Immunofluorescent study clearly demonstrated that the transplanted hepatocytes synthesized the albumin.

3. No detectable AFP was measured in sera.

4. ICG clearance test: half-life in the blood of rats with an ectopic liver was 5·92±0·92 min when compared with 7·37±0·31 min in control rats. The difference was statistically significant ($P<0·05$).

5. Ammonia tolerance test: the blood ammonia concentration immediately after the injection was lowered to a mean of 94·7 per cent of the initial value 15 min after the injection in rats with an ectopic liver. In control rats without an ectopic liver, it showed a mean of 28·7 per cent of the initial value.

An ectopic liver recomposed from isolated hepatocytes transplanted in the spleen of syngeneic rats for 1 year had the biological potential to synthesize albumin and glycogen. The differences between rats with and without an ectopic liver in Indocyanine Green clearance and ammonia tolerance tests can be evaluated as reflecting a functioning ectopic liver in the spleen.

86. Correlation of speech with tongue mobility and area resected after surgery

P. BRADLEY, L. HOOVER and P. STELL, *Department of Otolaryngology, University of Liverpool*

Fixation of the tongue and loss of mobility are said to interfere with articulation (Summers, 1974). Little information is available on the amount of tongue that can be removed before speech is seriously impaired.

Speech was measured by articulation scores of phonemes (Bradley et al., 1979). Forty-four patients who had undergone surgery to their tongue were studied.

Four parameters of mobility were measured: protrusion and lateral deviation of the tip of the tongue and elevation of the centre and base of the tongue.

The area of the tongue was assessed by measuring tongues taken at post mortem. Using this 'average' tongue the area of tongue remaining in the above 40 patients was measured as a fifth variable.

Multiple linear regression of the articulatory score against the above five predictor variables showed significant overall regression ($r=0·79$, $F_{5,34}=11·54$, $P<0·001$), but of the five variables only the area resected was significant ($t_{34}=2·82$, $P<0·01$).

The data were then reanalysed by linear regression in two groups—those with and those without replacement of the tongue by distant flaps. There was no statistical difference between the two slopes. The entire data were then combined giving the result: $\log_{10}$ articulatory score = 1·76 − 0·015 area resected.

From this it can be calculated that the articulatory score remains within intelligible limits until 24 per cent of the tongue has been resected. Replacement of bulk by a distant flap does not appear to improve articulation.

BRADLEY P. J., HOOVER L. and STELL P. M. (1979) Objective assessment of speech after surgery to the tongue. *Clin. Otolaryngol.* (In the press.)

SUMMERS G. W. (1974) Physiological problems following ablative surgery of the head and neck. *Otolaryngol. Clin. North Am.* **1**, 217–250.

87. Electrical sizing of cultured glial and nerve cells: a novel method for measurement of cell swelling

A. BAETHMANN and LUCRETIA CHAUSSY, *Institute for Surgical Research, Klinikum Grosshadern, University of Munich, 8 Munchen 70, Marchioninistr. 15, West Germany*

Cell swelling is a basic phenomenon in many kinds of tissue damage. Cytotoxic swelling of glial and nerve cell elements is an important component in brain oedema of various origins. However, no information is available so far, leading to an understanding of the mechanisms involved which would be necessary to develop specific therapeutic concepts. Progress in culture techniques of nerve cells and the availability of defined glial and nerve cell lines makes it possible to approach this problem experimentally. Volume measurements of single cells suspended in a medium can be accomplished with considerable precision. This laboratory employs an advanced cell sizing method (Metricell) which is based on the Coulter principle. A particle passing through a Coulter aperture impedes a current flowing through the same orifice. The change in voltage (pulse) produced by the particle is in proportion to the particle cross-section, and hence volume. Considering further parameters, (*a*) the applied current, (*b*) conductivity of the medium, (*c*) shape and resistance of the cell, (*d*) geometry of the aperture, cell volume can be directly computed employing a modified Maxwell equation.

The measuring system is fully computerized providing impulse-height analysis, online data storage and calibration, display of the current measuring process on a terminal and calculation of the mean cell volume and standard deviation. All pertinent data of an experiment are stored together with the complete volume histogram.

Swelling experiments of glial and nerve cells harvested after cultivation are conducted in a temperature controlled chamber. The chamber is persufflated with O_2, CO_2 and N_2 mixtures of any concentration desired. Po_2 and pH can be continuously monitored. Any condition suspected to prevail in the extracellular compartment in brain tissue after mechanical damage, ischaemia or severe general metabolic derangements can be mimicked in the chamber, such as acidosis, hypoxia, high K^+ concentrations, hypo- or hyperosmolarity, in order to study the cellular swelling response. Determinations of intra- and extracellular concentrations of relevant metabolites and ions permit evaluation of membrane permeability changes and of underlying biochemical processes.

88. Is general anaesthesia really the cause of postoperative chest complications? A controlled trial of three methods of anaesthesia for herniorrhaphy

P. J. GODFREY, M. S. SHABESTARY, J. GREENAN, MARY EVANS and A. V. POLLOCK, *Scarborough Hospital, North Yorkshire*

In an attempt to assess the respiratory effects of general anaesthesia as opposed to those of an incision through the abdominal parietes, we used a standard method of inguinal herniorrhaphy and randomized the type of anaesthetic.

Eighty-six patients were randomly allocated to general (GA), epidural (EA) or local infiltration anaesthesia (LA). Respiratory function was tested by spirometry (FEV_1 and FVC) and estimation of PaO_2 before and 4 h and 24 h after operation.

In the GA group 59 per cent of the patients had a 4 h FEV_1 <80 per cent of their preoperative figure, compared with 33 per cent of those after LA ($\chi^2=3{\cdot}85$, $P<0{\cdot}05$). The corresponding figures at 24 h were 41 per cent and 10 per cent ($\chi^2=7{\cdot}25$, $P<0{\cdot}01$). After EA 48 per cent of patients at 4 h and 46 per cent at 24 h had FEV_1 <80 per cent of their preoperative level, but the figures were significantly different from the LA group only at 24 h ($\chi^2=9{\cdot}28$, $P<0{\cdot}01$).

FVC was more often depressed after GA than after either EA or LA but the differences were not significant. Pao_2 did not deviate significantly from preoperative readings in any of the groups.

We conclude that general anaesthesia does play a part in the respiratory depression after abdominal operations.

89. Autotransplantation of small intestine to replace the thoracic oesophagus in adult dogs and puppies: an experimental study with 1-year follow-up

J. D. MEEUWIS, J. C. MOLENAAR and D. L. WESTBROEK, *Laboratory for Experimental Surgery and the Department of Paediatric Surgery, Erasmus University, Rotterdam, The Netherlands*

The technique to reconstruct a defect in the oesophagus by autotransplantation of intestinal segments as reported first by Seidenberg in 1959 has been used only in the cervical region.

The aim of this experimental study was first to investigate the applicability of this technique in a modified form for bridging a gap in the thoracic oesophagus and secondly to evaluate this procedure in small fast-growing individuals. A follow-up period of 1 year was planned. The first part of the experiment consisted of a group of 20 young adult beagles, mean weight 11·6 kg. In the second part the operation was carried out on 11 mongrel puppies, 8–12 weeks old, mean weight 9·3 kg.

In all cases an ileal segment was used. This required a 10–30 per cent resection of the total small bowel length. The mesenteric artery was anastomosed end-to-end to the internal mammary artery with a continuous 7/0 silk suture in the adult dogs and with an interrupted 7/0 silk suture in the puppies. The mesenteric vein was anastomosed to the superior caval vein with a continuous 7/0 silk suture in all cases. Four to six cm of the mid-thoracic oesophagus were resected and replaced by an ileal segment of equal length. All oesophago-ileal anastomoses were performed with a two-layer chromic catgut suture.

In the adult group 7 dogs and in the puppy group 4 dogs died. In each group 1 dog died of untreated shock and 6 adult dogs and 3 puppies of necrosis of the transplant by vascular thrombosis.

The remaining 20 dogs, 13 adults and 7 puppies, were followed-up. In one adult dog after total necrosis of the transplant a stricture was found. In the other 19 dogs (12 and 7) vascular patency was confirmed by angiography. Repeated oesophagoscopies showed no stricture and normal peristalsis of the transplant could be observed in all cases. Radiography at regular intervals showed good passage of contrast except in 2 puppies. In both cases a functional stenosis of the transplant was seen with enormous dilatation of the proximal oesophagus. As a result of this complication 1 was sacrificed at 19 weeks.

The adult dogs could eat adequately, kept their operation weight and were clinically in good shape. Five puppies could eat adequately and reached their estimated adult weight 3–6 months after operation with a weight-gain of 33–125 per cent. One puppy, with functional stenosis, needed special care to maintain his body weight slightly above the operation weight.

All dogs were sacrificed 1 year after the operation.

Post-mortem angiography showed extensive transanastomotic circulation at the oesophago-ileal connections.

Histological studies showed that the structure of the oesophageal wall and ileal wall was normal.

90. The cytological diagnosis of thyroid swellings

A. J. WEBB (Introduced by R. C. N. WILLIAMSON), *Department of Surgery, Bristol Royal Infirmary, Bristol*

Despite its unpopularity with British surgeons, fine needle aspiration biopsy of the thyroid is a simple technique offering precise identification of goitres (Bain and Crockford, 1978). Several comprehensive reports attest its reliability (Einhorn and Franzén, 1962). For 12 years this technique has been evaluated in surgical practice. Basic thyroid cytology was learned from imprint smears of 54 varied thyroidectomy specimens. Thereafter fine needle biopsy and cytological examination was included with conventional thyroid investigations in the diagnosis of 204 goitres, 128 of which were confirmed histologically. The entire series was carefully followed up.

There were no technical failures and minimal complications. All 36 cases of histologically confirmed neoplasm had been detected by preoperative cytological study, while benign follicular adenoma (8 cases) was successfully differentiated from carcinoma (25) and non-Hodgkin's lymphoma (3). Cytology correctly predicted the histological type in 26 of 28 malignant goitres. Among 168 non-neoplastic swellings, the cytodiagnostic features of nodular (115 cases) or toxic (11) goitre and of Hashimoto's (28) or de Quervain's thyroiditis (4) were clearly recognized on the aspirate smear, thus frequently avoiding surgical intervention.

Since many thyroid cancers present as goitres that feel benign, accurate clinical evaluation must remain difficult even in experienced hands. Fine needle aspiration biopsy of the thyroid is reliable and safe and provides valuable diagnostic information.

91. Acute stress ulcer: an experimental study

T. TOBE, T. YAMAGUCHI and H. YAJIMA, *Department of Surgery, Kyoto University Medical School, Kyoto, Japan*

Acute stress ulcer is one of the most troublesome problems for surgeons because of its sudden onset, massive haemorrhage, poor risks due to background condition and low operative success.

This paper presents an experimental study of pathophysiology from the viewpoint of secretion and prevention using (synthetic) gastric inhibitory polypeptides.

A total of 400 rats weighing approximately 200 g each was given restraint ulcers and divided into four groups: (*a*) control group, (*b*) surgically vagotomized group, (*c*) medically vagotomized group, (*d*) gastric inhibitory polypeptide (synthetic GIP, synthetic neurotensin and synthetic somatostatin) infused group. The stomachs were examined by light and electron microscopy.

In the control group (*a*) approximately 85 per cent of the rats showed gastric bleeding and erosion. In the surgically vagotomized group (*b*) only 10 per cent showed ulcer formation. In the medically vagotomized group (*c*) (atropine and hexamethonium bromide) there was no ulcer formation. In the group infused with gastric inhibitory polypeptides (*d*) there was little or no ulcer formation (GIP 40 per cent, somatostatin 0 per cent).

In stomachs with ulcers both exocrine cells (parietal and chief cells) and endocrine cells (G cells and EC cells) showed evidence of hyperfunction by electron microscopy; in the ulcer-prevented groups these cells were in a state of hypofunction.

These findings indicate that continuous intravenous infusion of synthetic somatostatin will be effective in the prevention of stress ulcers in poor risk patients.

94. Oral mannitol for mechanical bowel preparation

S. MINERVINI, I. A. DONOVAN, J. ALEXANDER-WILLIAMS and M. R. B. KEIGHLEY, *The General Hospital, Birmingham*

Conventional mechanical bowel preparation with enemas and purgatives is not always effective and takes 3–5 days. Whole bowel irrigation (WBI) with normal saline delivered through a nasogastric tube is rapid and efficient, but unpleasant to the patient and associated with sodium and water retention (Crapp et al., 1975). Oral mannitol may reduce the electrolyte disturbances of whole bowel irrigation (Donovan et al., 1978).

We have developed a method of oral bowel preparation with mannitol and water (group A) which avoids a nasogastric tube. Results have been compared with patients having WBI with mannitol (group B) or WBI alone (group C). In group A ($n = 20$) preparation was successful in all except four patients, 2 with a small lumen diameter (<5 mm). In group B ($n = 21$) preparation was successful in all but 2 patients who vomited. In group C ($n = 20$) 6 patients had inadequate bowel preparation. The mean duration of preparation was 3·9 h for group A, 3·4 h for group B and 4·5 h for group C. The mean fluid gain was 305 ml for group A, 1160 ml for group B and 2700 ml for group C. The mean sodium gain was 200 mmol for group A, 324 mmol for group B and 564 mmol in group C.

These results indicate that oral mannitol is effective and is more acceptable to patients than WBI and avoids the problem of fluid and sodium retention.

95. Gastrointestinal adaptation in patients with ileostomy

S. SAGAR, R. BENNETT and R. SHIELDS, *Departments of Surgery and Nuclear Medicine, University of Liverpool and Royal Liverpool Hospital*

Patients are said to adapt to the loss of the colon by reducing the volume of the ileostomy effluent. One possible mechanism for this 'adaptation' is a reduction in gastrointestinal transit, allowing more time for absorption.

We have studied gastric emptying and intestinal transit times in patients with established ileostomy using ^{99}Tc-labelled bran as a marker of transit of food. Bran is an ideal vehicle, being a natural dietary residue, and our *in vivo* and *in vitro* studies show that the bran–technetium bond is stable in gastrointestinal secretions.

Gastric emptying was measured using the gamma camera method in 30 patients (15 with ileostomy and 15 normal controls) after ingestion of a marker incorporated into a meal. The mean rate of gastric emptying was 0·74 per cent per minute in ileostomy patients, not significantly different from 0·84 per cent per minute in normal controls. Gastric residue at 90 min was 38 per cent of the meal in ileostomy patients compared to 25 per cent in the normals.

Mouth to stoma transit times were compared with mouth to caecum transit times in controls. In 8 out of the 10 controls, the peak transit time (mouth to caecum) was 4 h or less; however, in all the ileostomy patients ($n = 15$) the peak transit time lay between 4 and 8 h ($P < 0{\cdot}001$ χ^2 with Yates' correction).

Our data supports the hypothesis that there is a delay in gastrointestinal transit in patients with established ileostomies. This delay allows increased time for absorption of fluid and electrolytes.

96. Natural history of perianal Crohn's disease

P. BUCHMANN, R. N. ALLAN, M. R. B. KEIGHLEY and J. ALEXANDER-WILLIAMS, *The General Hospital, Birmingham*

Perianal disease is a frequent presentation of regional enteritis but in our experience these lesions often remain quiescent for many years.

The aim of this study has been to examine the natural history of perianal Crohn's disease from a 10-year follow-up of 109 patients with histological Crohn's disease and anal lesions. Fourteen patients (13 per cent) have died from unrelated disorders. Ten have acquired excision of the rectum but only 5 for perianal disease (4·5 per cent). Of the remaining 85 patients, 61 have been followed up by proctoscopy and rectal biopsy. Anal tags were still evident in 25 of 37 patients (68 per cent) but new tags had appeared in 2 patients. Only 10 of 53 fissures (19 per cent) were still present at 10 years and there were no new fissures. Fistulas were still present in 7 of 21 subjects (33 per cent) but were asymptomatic, the remainder had healed spontaneously ($n = 8$) or following operation ($n = 6$) and new fistulas had appeared in only 5 patients. The one patient with a stricture still has a stricture, but anal stenosis has developed in 29 patients, 27 of whom had had a fissure. None of the patients have become incontinent.

These results indicate that perianal manifestations of Crohn's disease pursue a relatively benign course and are rarely an indication for proctectomy.

97. Effect of 5-fluorouracil [5FU] on pancreatic protein secretion: its rationale in the treatment of acute experimental pancreatitis

D. M. J. GEEWATER (Introduced by H. D. RITCHIE), *Surgical Unit, The London Hospital, London*

It has been postulated (Knight and Condon, 1971) that drugs which inhibit protein synthesis might be useful in the treatment of acute pancreatitis. Three studies are described in which an attempt was made to investigate the action of the chemotherapeutic drug 5FU in this context.

1. Effect on pancreatic protein secretion: in six experiments using the isolated perfused canine pancreas (Hermon-Taylor, 1968), it was found that 5FU significantly inhibited total pancreatic enzyme output ($P<0{\cdot}01$).

2. Effect on pancreatic protein secretion coupling: as cyclic GMP has been postulated to control release of zymogen granules containing exportable proteins (Albano, 1976) an attempt was made to determine the effect of 5FU on cyclic GMP and zymogen granule discharge in guinea-pig pancreatic lobules. In six experiments 5FU significantly reduced tissue levels of cyclic GMP ($P<0{\cdot}01$) and inhibited release of zymogen granules ($P<0{\cdot}01$).

3. Effect on acute experimental pancreatitis: 10 guinea-pigs with a Pfeffer loop showed histological evidence of acute pancreatitis within 12 h.

In 10 guinea-pigs 25 mg of 5FU were given i.v. 3 h after the loop was created. At 12 h there was no histological evidence of acute pancreatitis.

From these studies it would appear that 5FU could prove to be of value in the treatment of developing acute pancreatitis.

98. Pentagastrin-stimulated gastric acid and the recurrence rate in a prospective study of duodenal ulcer patients treated by vagotomy

J. ØRNSHOLT, D. ANDERSEN and E. AMDRUP, *Surgical Gastroenterological Departments L, Kommunehospitalet, and K, Amtssygehuset, University of Århus, Denmark*

In a prospective study of 906 duodenal ulcer patients allocated randomly to either parietal cell vagotomy or selective gastric vagotomy (The Århus County Vagotomy Trial) the pentagastrin-stimulated acid secretion capacity was investigated before, at 3 months and at 1 year after the operation. The clinical status was assessed once a year. This study aims to investigate a possible relationship between the preoperative acid secretion and the alteration in acid secretion during the first year following vagotomy and to compare the secretion pattern to the recurrence rate.

The data from 754 patients are analysed. They were divided into three groups according to the reduction in the pentagastrin-stimulated peak acid output (PAO_{pg}) as measured 3 months after the operation. In 77 patients (10 per cent) the reduction was less than 20 per cent and in 303 patients the reduction was 20–60 per cent, while the reduction was greater than 60 per cent in 374 patients (50 per cent). Patients with the greatest postoperative reduction had the highest preoperative PAO compared to those with poor or no reduction ($P<0{\cdot}0004$). This pattern was identical after PGV and SGV. A highly significant rise in PAO from the third to twelth month was found in the group with the initial reduction of more than 60 per cent ($P<0{\cdot}0001$). In the group with no reduction a decrease of 23 per cent was seen in the mean PAO during the first year of observation ($P<0{\cdot}0001$). No alteration occurred in the mean values for the patients in the intermediate group.

The variation in basal acid secretion showed the same pattern.

The patients in the three groups showed identical dispersion on the Visick scale. The recurrence rate up to date is 7·3 per cent in the series, but 14 per cent in the group with no reduction against 4 per cent in the group with more than 60 per cent reduction ($P<0{\cdot}0005$). The recurrence rate in the intermediate group was 9·6 per cent.

The degree of postoperative reduction in gastric acid secretion and its variation with time seems to reflect biological differences more than difference in surgical technique. The highest recurrence rate was found in the group with no reduction.

99. Effect of histamine and histamine antagonists on acid secretion and mucosal blood flow in man

S. E. KNIGHT, R. L. MCISAAC and C. D. RENNIE, *Academic Surgical Unit and Department of Physiology, St Mary's Hospital Medical School, London*

Gastric mucosal blood flow (GMBF) and acid secretion increase together during stimulation with pentagastrin (Knight et al., 1978). The purpose of this study was to investigate the effect of histamine on acid and GMBF in man, with and without H_1 and H_2 receptor blockade.

Seven male volunteers (aged 22–36) were given histamine in four doses ($1{\cdot}57$–$12{\cdot}2\times10^{-6}$ mol kg^{-1} h^{-1}) each for 30–45 min. The studies were repeated with an infusion of either mepyramine ($2{\cdot}5\times10^{-6}$ mol kg^{-1} h^{-1}) beginning 30 min before histamine. Maximal output of acid and of GMBF (estimated using neutral red clearance) was calculated, as well as the dose of histamine giving half-maximal output (ED_{50}) according to Parker and Waud (1971). Maximal acid output was $310\pm21{\cdot}1$ µmol H^{+} min^{-1} and GMBF was $58\pm3{\cdot}9$ ml min^{-1}.

The ED_{50} (mean±s.e. mean) is given in the Table.

$ED_{50}\times10^{-6}$ mol kg^{-1} h^{-1}	Acid	GMBF
Histamine	$3{\cdot}4\pm0{\cdot}66$	$2{\cdot}4\pm0{\cdot}39$
$^{+}$mepyramine	$2{\cdot}8\pm0{\cdot}57$	$1{\cdot}4\pm0{\cdot}21$
$^{+}$cimetidine	$9{\cdot}3^{**}\pm0{\cdot}88$	$2{\cdot}8\pm0{\cdot}41$

** $P<0{\cdot}05$ compared to histamine alone (analysis of variance compared to regression).

Mepyramine had no effect on either acid or GMBF and at the dose used cimetidine did not affect GMBF. We conclude that the gastric vasculature is less sensitive to cimetidine than the parietal cell in man.

100. Total body hyperthermia induced by a computerized microwave technique: studies in normal and tumour-bearing rats

P. E. JOHNSSON, L. HAFSTRÖM, M. BOLMSJÖ and B. PERSSON, *Departments of Surgery and Radiation Physics, University of Lund, S-221 85, Lund, Sweden*

The selective lethal effect of supranormal temperature on malignant cells is well documented. Different methods of hyperthermia to induce tumour necrosis have been developed —water bath immersion, microwave, ultrasound and hyperthermic regional perfusion. Most information on microwaves concerns application for local hyperthermia. The temperature and length of exposure and how to fractionate the microwave heat for maximum tolerance and effectiveness are not established. In this communication total body hyperthermia induced by microwave has been tested.

Wistar rats (200 g), with or without transplantable adenocarcinoma in the liver, were used under ether anaesthesia. A Pt/Ir thermocouple was placed retroperitoneally adjacent to the aorta with the tip below the diaphragm. The animals were kept isolated in a plexiglas cage, which was placed in a larger plexi cage with a constant temperature (25 °C). Siemens (Radioterm 305) Magnetron at 2·45 GHZ max and 200 W microwave generator was used. The exposure was below 4000 W/m^2. The temperature probe signal from the animal was digitalized and fed to a computerized control system (INTEL 8085 microprocessor) with 16 Kbyte memory. This system directed the microwave generator through a set of relays to a predetermined temperature in the animals of 41·5 °C or 42 °C for 1 or 2 h three times per 24 h. The microwave generator was turned off for a period of 4 s before the temperature reading to avoid microwave-induced interference. The temperature was recorded each 30 s. The temperature in the animals was also recorded in other parts of the body. The influence of hyperthermia on the survival and on tumour growth was registered.

The computerized microwave generator induced a precise hyperthermia (±0·2 °C) to a predetermined temperature for exact duration and intervals. The temperature registered in other parts of the body varied in relation to the guiding probe (±1 °C). The central temperature of 41·5 °C for 1 h three times per 24 h caused a 70 per cent survival. Longer duration or higher temperature increased the mortality significantly. No difference in survival between tumour-bearing and non-tumour-bearing rats was seen. A reduced tumour growth was observed during the first 3 days after hyperthermia.

A computerized microwave technique has been shown to induce a precise hyperthermia in experimental animals. The central temperature of 41·5 °C for 1 h three times per 24 h gives acceptable mortality in the experimental animals. A reduced tumour growth after this type of hyperthermia was observed.

101. Thyrotropin (TSH) binding and adenylate cyclase stimulation in normal and adenomatous thyroid tissue

O. H. CLARK, T. C. COTE and R. A. NISSENSON, *Veterans Administration Medical Center, San Francisco, and Department of Surgery and Medicine, University of California Medical Center, San Francisco, California, USA*

Previous studies showed that TSH binds to TSH receptors both in normal and neoplastic thyroid tissue. This investigation compared TSH binding with a known biological action of TSH; i.e. adenylate cyclase (AC) responsiveness to TSH ^{125}I bovine TSH (specific activity 11 to 15 μCi/μg) was incubated with an 8000 *g* particulate fraction of normal (NT) or adenomatous (A) thyroid tissue rich in thyroid plasma membranes. AC stimulation, and protein concentration, were measured by standard methods.

Results: 1. Total TSH binding amounted to 9·26 per cent of total radioactivity for NT and 13–19 per cent for A. Non-specific binding was 0·5–1·3 per cent. 2. Total binding reached a plateau within 30 min at 30 °C and remained stable in both NT and A for 3 h. 3. Particulate fractions prepared from frozen tissue showed a marked decrease in TSH-stimulated AC but TSH binding persisted. 4. AC stimulation (per mg prot.) in response to TSH and fluoride was about three times greater in frozen 8000 *g* particulate prepared from fresh thyroid tissue when compared to whole homogenate. 5. Basal AC activities (pmol/30 mg prot.) in NT 15·0±1·0 and A 11·3±8·1 (mean±s.d.) were comparable. 6. The TSH concentration required to produce half maximal TSH stimulation of AC was comparable in NT and A (3·5 mU/ml) but maximal stimulation in A was always equal or greater than in NT. 7. Hormone specificity of the TSH receptor was demonstrated since TSH binding was not inhibited and AC not stimulated by hGH, hFSH or hLH. 8. NT and A generally had two orders of binding sites. 9. Binding dissociation constants for high and low affinity sites in NT (Kd_1 $4·8\times10^{-10}$, Kd_2 $4·5\times10^{-8}$) and A (Kd_1 $3·1\times10^{-10}$), (Kd_2 $6·8\times10^{-8}$) were comparable but binding capacities (pg/μg particulate protein) were higher in NT (n_1 57·6, n_2 3750) than in A (n_1 14·9, n_2 708).

It is concluded that (*a*) benign thyroid adenomas have TSH receptor sites that exhibit a biological response (AC stimulation) to TSH; (*b*) Adenomas have fewer high affinity binding sites but greater AC stimulation to TSH than NT; (*c*) TSH binding and AC stimulation can occur under the same experimental conditions.

102. The patient with abdominal pain and negative investigations: discharge or laparoscopy

R. A. B. WOOD and A. CUSCHIERI, *Department of Surgery, Ninewells Hospital and Medical School, Dundee*

The patient discharged from hospital with undiagnosed abdominal pain has a 56·9 per cent chance of more pain within 3 years and in the over 50s age-group a 10 per cent chance of subsequently developing cancer (McAdam et al., 1978). A series of patients is reviewed with chronic persistent or recurrent abdominal pain and a negative barium meal and follow-up examination referred by consultant physicians for a surgical opinion.

There were 102 patients, age range from 17 to 70 years (mean age 46). All patients were laparoscoped under general anaesthetic with CO_2 insufflation. The findings in the peritoneal cavity were noted and if laparotomy was thought necessary, this was performed under the same GA. Follow-up of the rest of the patients was from 4 years to 6 months. Significant pathology other than adhesions and ovarian cysts was observed in 25 patients. These included inflammatory bowel disease, 5 patients (mean age 33) and intra-abdominal malignancy, 7 patients (mean age 64). The diagnosis was missed in 2 patients despite laparoscopy.

The results of this survey indicate that 25 per cent of patients with chronic persistent abdominal pain are found to have significant intra-abdominal pathology and that laparoscopy is a reliable investigation in establishing a firm diagnosis in these patients.

MCADAM W. A. F., WILSON D. H., MATHARU S. A. et al. (1978) Once a bellyacher, always a bellyacher? *Br. J. Surg.* 65, 818.

103. Delayed hypersensitivity response (DHR) and infections in surgical cancer patients

R. DIONIGI, F. GNES, A. BONERA, L. DOMINIONI and G. S. POSSATI, *Instituto di Patologia Chirurgica, Università di Pavia, 27100 Pavia, Italy*

Failure of DHR has been shown to be associated with an increased incidence of sepsis in surgical patients. The purpose of this study has been to evaluate DHR and the incidence of postoperative infections in surgical cancer patients. One hundred and fifty patients, 20–78 years old, with the preoperative diagnosis of cancer (stomach, 37; colon and rectum, 37; oesophagus, 4; pancreas, 7; breast, 24; lung, 18; melanoma, 12; skin, 6; hepatoma, 1; ovary, 1; uterus, 2; sarcoma, 1) have been skin tested before surgery with recall antigens (RA) and a primary antigen (PA). RA: intradermal injection of PPD, trichophyton, candida and streptokinase–streptodornase. PA: epicutaneous sensitization and challenge with DNCB. Readings were recorded by the same observer as mm of erythema and induration, and the responses were graded as: normergic, hypoergic and anergic. In order to identify possible causes of anergy and infection, the following parameters have been considered: preoperative serum albumin level, tumour stage, duration of anaesthesia and operative contamination. Fifty-four patients were recorded as normergic, 63 hypoergic and 12 anergic. The following surgical infections have been observed: urinary (26), respiratory (23), wound (20), thrombophlebitis (6), intra-abdominal abscess (6), central venous catheter (6), biliary (1), postoperative undiagnosed fever (10). One or more of these infections occurred in 37 per cent of the normergic patients, in 46 per cent of the hypoergic patients and in 83 per cent of the anergic patients. The incidence of infections in anergic patients is significantly higher than in the normergic group ($\chi^2 = 6·7$; $P<0·01$) and hypoergic ($\chi^2 = 4·2$; $P<0·05$) groups. Albumin concentration was significantly lower in anergic patients than in normergic (3·14±0·45 g/100 ml *v.* 3·50±0·46 g/100 ml; $P<0·05$). No correlation was found between DHR and stage of tumour. The incidence of respiratory infections only is significantly higher when duration of anaesthesia is longer than 120 min ($P<0·05$). In normergic patients the degree of operative contamination is associated with a significantly higher incidence of infections (infections in clean operation *v.* contamined: $\chi^2 = 5·2$; $P<0·05$); however, in anergic patients the incidence of infections is not different between clean and contamined procedures. In conclusion, cancer patients who are preoperatively anergic to skin tests present a higher risk of postoperative infections, regardless of degree of contamination. Anergy seems to be related more to nutritional status than to tumour stage.

104. Trial of adjuvant immunotherapy with *Corynebacterium parvum* in colorectal cancer

R. G. SOUTER, P. G. GILL and P. J. MORRIS, *Nuffield Department of Surgery, University of Oxford, Radcliffe Infirmary, Oxford*

Corynebacterium parvum is a potent stimulator of the reticulo-endothelial system, and is able to boost anti-tumour immunity in animal models. Patients with colorectal cancer have a poor prognosis even after curative surgery (Gill and Morris, 1978). Furthermore, many patients with colorectal cancer show a relative anergy even at early stages of the disease. Thus there is a rational basis for a controlled trial of immunotherapy in colorectal cancer aimed at treating microscopic disease presumed present at the time of surgery.

Patients with Dukes' B or C colorectal cancer were entered into the trial. Those over the age of 70, or known cases of cardiorespiratory disease or a history of allergies, were excluded from the trial. Patients were randomized into treatment with *C. parvum* or no treatment. Informed consent was obtained from patients receiving *C. parvum*. They were given killed *C. parvum* (Wellcome) i.v. at doses of $5\ \mathrm{mg/m^2}$ in normal saline over 30 min. Ten infusions were given over 2 years. Most patients suffer shivering accompanied by pyrexia 2–3 h after infusion and some become hypotensive in the first 12 h. A transient leucopenia and a depression in T lymphocyte numbers and PHA responsiveness occurred after the infusion, returning to normal levels within 48 h. However, a significant increase in blood monocytes, the precursors of macrophages, was seen at 7 days. To date 72 patients have been entered into the trial with the following outcome.

	Patients	Recurrences	Tumour deaths
C. parvum	34	5	2
No treatment	38	8	5

The trial is continuing, but it does not appear that *C. parvum* infusions are deleterious to patient outcome, and there is a suggestion of a beneficial influence.

GILL P. G. and MORRIS P. J. (1978) The survival of patients with colorectal cancer treated in a regional hospital. *Br. J. Surg.* **65**, 17–20.

105. The effect of diversion of duodenal contents on the production of experimental gastric ulcer

T. J. WIEMAN, M. H. MAX, C. R. VOYLES and G. BARROWS (Introduced by H. C. POLK JUN.), *Price Institute of Surgical Research, Department of Surgery, University of Louisville School of Medicine, Louisville, Kentucky, USA*

The production of chemically induced gastric cancers in rats is enhanced following vagotomy and gastroenterostomy (Morgenstern, 1968). This and similar operations in man are allegedly followed by a significant increase in the development of gastric cancers (Gazzola and Saegesser, 1975). Reflux of biliary and pancreatic secretions is said to be a contributing factor in the induction of these neoplasms. The present study was designed to test whether diversion of duodenal contents after vagotomy and gastroenterostomy would decrease the expected incidence of experimental gastric carcinomas in rats.

Two hundred and forty animals were divided into three groups of 80 each: group 1 animals (controls) had 0·9 mg of 3-methylcholanthrene injected submucosally into the gastric antrum. Group 2 animals (TV+GE) underwent bilateral truncal vagotomy and gastroenterostomy; the carcinogen was injected into the gastric submucosa near the anastomosis. Group 3 animals (TV+GE+Div) were prepared precisely as group 2 animals except that total duodeno-enteric diversion was added. After 8 months, all surviving animals were sacrificed and studied. Blind histopathological examination of the injection site disclosed:

Group	Surviving operations	Death after 1st week*	Developed cancer
1. (Control)	60	0	6 (10%)
2. (TV+GE)	71	4	23 (33%)
3. (TV+GE+Div)	27	4	7 (26%)

* χ^2 not significant at 0·1.

Groups 2 and 3 had an increased incidence of gastric cancer compared to group 1 ($P = 0{\cdot}012$). Groups 2 and 3 did not differ from one another in this regard ($P = 0\ 8$).

The data confirm a greater incidence of chemically induced gastric adenocarcinoma in rats that underwent vagotomy and gastroenterostomy. However, diversion of duodenal contents away from the gastroenterostomy does not protect the animal from this increased risk.

106. Effect of prostaglandin inhibitors and diphosphonates on tumour-mediated osteolysis

A. W. SAMUEL, STELLA RUSHTON and C. S. B. GALASKO, *Department of Orthopaedic Surgery, University of Manchester, Hope Hospital, Manchester*

Previous studies have indicated that there are two phases to the bone destruction which occurs with skeletal metastases. The earlier phase is mediated via the osteoclast, the tumour-secreting osteoclast stimulating factors, which include prostaglandin. In animal experiments prostaglandin inhibition has significantly reduced the prostaglandin activity in the tumour, osteoclast production and the amount of bone destruction.

The current studies were designed to determine whether prostaglandin inhibitors had an effect on human tumours and whether other agents which affect osteoclast production but do not affect prostaglandin activity inhibit tumour osteolysis. One mm cubes taken from 27 mammary cancers were cultured against mouse calvarium, different prostaglandin inhibitors, in varying dosage, being added to the culture medium (Table). In 15 experiments diphosphonates were added. These drugs directly affect bone turnover.

Twenty specimens of the VX2 carcinoma were studied in the same way. The results (Table) indicated that prostaglandin inhibitors produced a significant reduction in tumour osteolysis. Diphosphonates were as effective but combining the two agents did not enhance the effect.

The findings suggest that agents which inhibit osteoclast production will reduce tumour-mediated osteolysis irrespective of their mechanism of action.

107. Kidney graft survival after donor pretreatment in dogs receiving peroperative transfusions

C. J. VD LINDEN, W. A. BUURMAN, A. S. FABRICANT, J. JEEKEL and J. M. GRENIER, *State University Limburg, Hospital St Annadal, Maastricht, Holland*

Kidneys of drug-treated donors have a better survival time compared with controls in several species. In man donor pretreatment gives a better graft survival, according to some authors. The data of several prospective trials on donor pretreatment, however, made the benefit of the treatment questionable. Little is known about the mechanisms which underlie the retarded rejection induced by donor pretreatment.

We investigated the *in vivo* effect of a peroperative transfusion with 100 ml fresh complete donor blood, 100 ml leucocyte-free donor blood (erythrocytes, thrombocytes and plasma) and with pure lymphocytes obtained from 100 ml donor blood on pretreated kidneys in dogs. The kidney graft survival data of these groups were compared with the data of untreated kidneys in recipients receiving 100 ml donor blood peroperatively and of pretreated kidneys in recipients receiving 100 ml third party blood peroperatively.

Pretreatment consisted of 50 mg/kg BW procarbazine and 50 mg/kg BW methylprednisolone 5 and 2½ h before harvesting. Donor blood was taken from the donor just before treatment.

	Mean survival	No.
1. Donor pretreatment	26·7	7
2. Donor pretreatment + 100 ml donor blood	12·1	6
3. Donor pretreatment + 100 ml leucocyte-free blood	12·7	7
4. Donor pretreatment + pure lymphocytes of 100 ml blood	13·1	7
5. Donor pretreatment + 100 ml third party blood	18·8	6
6. Control + 100 ml donor blood	12·0	7
7. Control	13·0	8

All recipients received postoperatively 2 mg/kg BW azathioprine, 2 mg/kg BW prednisolone every day.

Our results showed that a peroperative transfusion with a relatively large dose of donor specific antigens with or without active lymphocytes or a relatively small dose of donor specific lymphocytes abolished the improved graft survival induced by donor pretreatment.

In contrast with these results the survival time of pretreated kidneys with a peroperative transfusion with a relatively large dose of third party specific antigens and active lymphocytes was significantly prolonged and did not differ significantly from the survival time of donor pretreatment alone.

108. The role of thymus and spleen in enhanced allograft survival

N. L. TILNEY, L. K. BIRINYI JUN., W. S. HENDRY, W. M. BALDWIN III and MARY GRAVES, *Departments of Surgery and Pathology, Peter Bent Brigham Hospital, Boston, Mass., USA*

The role of the thymus and spleen in enhanced allograft survival is unclear (Tilney and Bell, 1974; Stuart et al., 1976; Batchelor et al., 1977; Tilney et al., 1978). Lewis rats reject L×BN hearts in 7 days. Graft survival is enhanced to 22 days by pretreatment with BN splenocytes and Lewis anti-BN antisera 11 and 10 days before transplantation, respectively. Splenectomy prior to enhancement decreased graft survival to 15 days ($P<0.05$). When splenectomy was delayed until (*a*) just after enhancement, (*b*) at the time of grafting or (*c*) 1 week after grafting, graft survival was unaffected. However, splenectomy 14 days after grafting prolonged graft survival (MST >40 d, 40 per cent surviving >80 d). Thymectomy before enhancement or at the time of grafting did not affect graft survival. Thymectomy 6 or 10 d after grafting decreased enhanced graft survival. Thymocytes harvested from these rats 6 days after transplantation transferred prolonged graft survival to unmodified rats (MST = 17 d). Thus, the spleen is required for optimal initiation of enhancement via antigen and antibody pretreatment. Following grafting the thymus is involved in maintaining enhanced graft survival and the spleen in terminating it.

109. Potential relationship between Ir genes and Ia antigens expressed on antigen-presenting macrophages

J. E. NIEDERHUBER, *Departments of Surgery and Microbiology, University of Michigan Medical Center, Ann Arbor, Michigan, USA*

The immune response to thymus-dependent antigens depends on the presence of Ir genes located within the I region of the H_2 major histocompatibility complex. The I region also controls expression of membrane alloantigens (Ia) expressed on lymphocytes and antigen-presenting macrophages (Mϕ). Experiments were conducted to examine the relationship of Ir genes to Ia antigens at the level of Mϕ-T cell interaction during induction of an antibody response.

Antigen-presenting Mϕ were purified from spleens of [B10.A(3R)×B10.A(5R)] F_1 mice, two strains that differ only at the I–J subregion or in other experiments from [B10.S(9R)×B10.HTT] F_1 mice which also differ at I–J. T–B cells were purified from each parental strain and from F_1 spleens. Mϕ (J^k/J^b) or $\overline{J^k/J^s}$) were incubated with B10.A(3R) anti-B10.A(5R) sera (anti-J^k) for 30 min, washed with fresh media and cultured with the different T–B cell sources plus burro red cells. The number of plaque-forming cells (PFC) was determined on day 5.

F_1 Mϕ blocked with antibodies to I–J	T–B cell source	[PFC/dish ± s.d.] Exp. 1	Exp. 2
Inappropriate anti-Ia	F_1	799±48	670±46

Anti-I–J^s	F_1	1139±65	1548±100	696±33
Anti-I–J^s	B10.S(9R)	1251±106	1456±71	801±89
Anti-I–J^s	B10.HTT	489±20	488±54	42±28

F_1 appropriate for experiment: [B10.A(3R)×B10.A(5R)] F_1 or [B10.S(9R)×B10.HTT] F_1.
All results: mean quadruplicate cultures ± s.d.

These results support the concept that the T cell possesses a restricted receptor which must recognize an appropriate I–J subregion determinant on the Mϕ for efficient induction of a primary antibody response and suggest a mechanism of Ir gene function.

110. Effect of ALG on suppressor-lymphocytes *in vitro* (cultures) and *in vivo* (kidney transplant patients)

C. HAMMER, W. BULLINGER, W. LAND and W. BRENDEL, *Institut fur Chirurgische Forschung, Klinikum Grosshadern, Marchionistr. 15, 8 Munich 70, West Germany*

The suppressive activity of regulator-lymphocytes is supposed to play a beneficial role in protecting a graft from rejection. As immunosuppressive therapy (IST) in kidney transplantation reduces lymphocytes (LY) in peripheral blood (PB), especially when combined with ALG, it was the aim of this study to monitor the fluctuations of LY populations in respect to suppressor cell function under such a therapy.

Thirty-five kidney recipients received a combination of 5 mg/kg BW azathioprine 100 mg prednisolone reduced to 30 mg after 2 months and ALG, 20 mg protein/kg BW over 10 days after transplantation. A basic therapy of 2·5 mg azathioprine and 15 mg cortisone was continued for 8 months. WBC-count shifting of T–B cells in PB, circulating levels of ALG and ALG bound to LY surface were monitored at 3-day intervals. The effect of IST and the action of ALG only, on 'Suppressor cells', was measured in an *in vitro* assay with patients' peripheral LY and cells from healthy donors. This suppressive influence of 'spontaneous' and 'Concavalin A activated' circulating suppressor cells on patients on MLC and mitogen stimulation (PHA, PWM, Con A) was recorded preoperatively, under IST with and without ALG, and during rejection episodes. The effect of various concentrations of ALG-LY of healthy donors was measured with 'MLC-specific' suppressor cells' in MLC and mitogen stimulation.

			R	
		Preop.	No ALG	ALG
MLC/Spont.	Lys*	24%	+134%	+130%
MLC/Activ.	Lys	41%	13%	19%
PHA/Spont.	Lys	29%	14%	+132%
PHA/Activ.	Lys	39%	50%	27%

			No R	
			ALG	No ALG
MLC/Spont.	Lys*	24%	+117%	31%
MLC/Activ.	Lys	41%	4%	59%
PHA/Spont.	Lys	29%	21%	46%
PHA/Activ.	Lys	39%	30%	54%

R, Rejection.
* Lys ≙ Spontaneous and activated suppressor lymphocytes.

No changes in cell counts and activity were found preoperatively. After transplantation and especially after ALG, LY counts drop to 40 per cent of initial values. As B cells remain relatively constant, T cells show the major reduction. ALG positive circulating LY decrease from 70 per cent preoperatively to 30 per cent after 7 days of ALG therapy. This reduction seems to include not only cytotoxic effect LY but also suppressor cells. Preoperatively values of spontaneous and activated suppressor cells are reduced during rejection, also in patients with rejection crises treated with ALG. In most patients the suppression of MLC and PHA response shifts to stimulation. Patients with well functioning grafts only under basic therapy recover quickly to show normal suppression. As ALG reduces the suppressive activity *in vivo*, tests were performed with ALG *in vitro*. LY incubated with LAG+rabbit complement for 1 h lose their MLC 'specific' and 'unspecific' suppressive activity with increasing ALG concentration. The results indicate, that IST and ALG hits cytotoxic as well as suppressor cells in patients and they show that the suppressive activity recovers quickly after reduction of IST or ALG.

111. Immune complex disease in mice and humans given *Corynebacterium parvum*

H. D. MITCHESON, J. UFF, B. A. PUSSELL and J. E. CASTRO, *Department of Surgery, Royal Postgraduate Medical School, Hammersmith Hospital, London*

Repeated infusions of *C. parvum* are used to treat human cancer. Renal failure has been reported in 3 patients (Dosik et al., 1977). In parallel studies in mice and humans we determined the effects of repeated doses of *C. parvum* on production of immune complexes and associated disease.

Mice received intravenous injections of 70 μg (human-equivalent dose) at weekly intervals for 4 weeks. Control groups were given a single low dose (70 μg) or a single high dose (466 μg) or no treatment. Thirty cancer patients were studied: 15 received *C. parvum* (10 mg/m²) by intravenous infusion monthly for 4 months; 15 received no treatment (controls).

Mice: Circulating immune complexes determined by Clq binding assay were significantly increased in mice that received repeated doses.

Immunofluorescent staining showed C(3) and IgG deposition in the kidneys and histology revealed a marked proliferative glomerulonephritis. These mice had microscopic haematuria but no elevation of serum urea.

Humans: Clq immune complexes were detected in those treated with *C. parvum*; 3 developed mild proteinuria and 12 microscopic haematuria with red cell and hyaline casts, the changes resolving over 3 days. Serum urea and creatinine remained normal.

We conclude that in mice repeated doses of *C. parvum* cause circulating immune complexes which are deposited in the kidneys causing renal disease. A similar pathology seems likely in humans.

112. Human K cell cytotoxicity is largely mediated by a T cell subset

J. KIRCHOFF, F. THOMAS, H. M. THOMAS, R. LEE and R. R. LOWER, *Medical College of Virginia, Richmond, Virginia, USA*

Both the surface receptors and the mechanisms of cytolysis of T (E-rosette and LMC cytotoxicity) and K (Fc receptor and anti-body-dependent-cellular cytotoxicity-ADCC) lymphocytes are distinctly different by classic teaching. We observed that anti-thymocyte globulin rendered T cell specific by B cell absorption depressed K cell type cytotoxity (ADCC). We, therefore, performed detailed *in vitro* and *in vivo* studies of the relationship of human T and K cells in macrophage-free cell preparations.

Results: 1. Surface receptor studies—using a sensitized ox erythrocyte rosetting test for Fc receptors, 87±4 per cent of thymocytes and 22±3 per cent of peripheral blood T cells can be shown to have IgM Fc receptors, whereas 33±8 per cent of thymocytes and 21±7 per cent of peripheral blood cells have IgG Fc receptors. 2. Clinical anti-human ATG given to humans causes a marked fall ($P<0{\cdot}05$) in ADCC activity. 3. Clinical ATG rendered T cell specific by B cell adsorptions and shown by *in vitro* testing to have T cell specificity significantly depresses K cell cytotoxicity ($P<0{\cdot}01$). 4. Depletion of human T cells by E rosette sedimentation significantly decreases K cell activity ($P<0{\cdot}05$). 5. Furthermore, the resulting T cell enriched reaction recovered by lysis of sheep cells can be shown to have a significant ($P<0{\cdot}01$) increase in K cell activity over unfractionated peripheral blood cells.

These studies support the concept that, in the human, the Fc receptor cell known to execute the majority of ADCC activity is a subpopulation of T cells. The findings are of theoretical interest and also may be important in developing suppressive agents to block human ADCC activity since surface receptors and function (Fc and ADCC) classically ascribed to K cells in the human are related to a T cell subset activity which appears to be blocked by agents such as ATG which have a relatively high degree of anti-T cell specificity.

113. Modulation of the immune response and control of tumour spread by a new synthetic compound

R. E. FALK, L. MAKOWKA, N. NOSSAL, J. A. FALK, J. E. FIELDS and S. S. ASCULAI, *Department of Surgery, University of Toronto and the Rotman Oncology Unit, Toronto General Hospital, Toronto, Canada and Monsanto Co., St Louis, Missouri* (*see* pp. 861–863)

114. Collagen formation by arterial smooth muscle cells after injury: an electron microscopic study

C. C. CHIDI and R. G. DEPALMA, *Department of Surgery, Case Western Reserve University Medical School, University Hospitals of Cleveland, Cleveland, Ohio, USA*

We have shown that collagen accumulates in thickened intima covered by regrowing endothelium following arterial injury (Chidi et al., 1979). We now compare sequential fine structural changes in non-endothelized and endothelized zones to test the hypothesis that endothelial cells (EC) might be a source of collagen. Changes in EC and smooth muscle cells (SMC) were characterized 2–60 days after a standard balloon injury of rabbit thoracic aorta.

In intima under regrowing endothelium, sequential fine structural changes showed transitional forms of SMC acquiring morphologic characteristics of fibroblasts (FB). Ultrastructural alterations of SMC were the development of nuclear lobulation, prominent Golgi and rough endoplasmic reticulum, loss of myofibrillae and appearance of many pinocytic vacuoles near cell membranes. Such changes were accompanied by abundant collagen deposition in close juxtaposition to transformed SMC. In contrast, zones not covered by endothelium exhibited only polygonal less active SMC: here collagen deposition was scanty. The presence of platelets, often within the arterial wall, also supported their postulated role as mediators of SMC proliferation (Ross et al., 1974). No ultrastructural evidence of collagen formation by EC was found.

Regrowing endothelium appears to stimulate transformation of SMC to FB after arterial injury. Collagen fibres selectively accumulate in such areas. Only transformed SMC, and not ECs, appear to secrete collagen after arterial injury.

115. Wound healing in stomach and duodenum during normal conditions and during long term cortisol treatment

F. GOTTRUP and H. OZLUND (Introduced by A. VIIDIK), *Department of Connective Tissue Biology, Institute of Anatomy, University of Aarhus, Aarhus, Denmark*

Few experimental studies have been published on the functional properties of wound healing in stomach and duodenum, confined to measurement of bursting and/or breaking strength. To obtain fuller and more detailed information, complete load-deformation curves were recorded and the development of the distribution of collagen in the healing area was measured. Furthermore, the effect of long term corticosteroid treatment was investigated, as little is known about the effect of these hormones on wound healing in the gastrointestinal tract.

One hundred and fifty male Wistar rats about 5 months old were used. Incisional wounds were made in the stomach (in the non-glandular part or rumen [R], and in the glandular part or corpus [C]) and duodenum [D]. The wounds were immediately resutured with 6/0 propylene interrupted sutures. After 5, 7, 10, 20 and 40 days the sutures were removed and strips perpendicular to the incision line were tested in a materials testing machine. In a second series, strips parallel to the incision line were punched out and collagen distribution was determined. A third series of rats was treated daily with cortisol (8 mg/kg) or NaCl subcutaneously, starting 4 weeks before operation and continued throughout the experiment. Strips from R, C and D were tested 7 and 20 days postoperatively.

Of intact tissues R had the highest breaking energy (area under load deformation curves) as well as highest extensibility and collagen concentration. There were only small differences between C and D except for breaking energy, which in C was twice the value of D. Of healing wounds from C and D both breaking strength and breaking energy were significantly higher than of intact tissues after 40 days. In R breaking strength reached the intact value, while the breaking energy reached only 75 per cent after 40 days. The stiffness of all types of wounds was higher after 40 days compared to intact tissue. The collagen concentration showed a good correlation to the mechanical properties of the wounds and the biochemically active zones were 4–6 mm on each side of the incisional line. Cortisol caused significant decrease in all tissues, the breaking energy (in per cent of the intact tissue value) for R: 16 (7 d) and 29 (20 d) (control wounds: 41 and 62), and for D: 21 (7 d) and 61 (20 d) (control wounds 52 and 106). Cortisol increased the incidence of microabscesses, but no wound ruptures occurred (non-absorbable sutures were used).

The normal healing of wounds in the glandular part of the stomach and duodenum is rapid, and the collagen concentration in these wounds is enhanced. The healing pattern of the non-glandular part of the stomach is different—the increase of mechanical strength is lower as is that of collagen concentration. The wound healing in all types of tissue is significantly impaired by systemic corticosteroid treatment.

116. Intrinsic contractility of human lymphatics is the main factor propelling lymph

W. L. OLSZEWSKI and A. ENGESET, *Surgical Research Laboratory, Polish Academy of Sciences, 02-004 Warsaw, and Norwegian Radium Hospital, Oslo, Norway*

According to the present state of knowledge, interstitial fluid and lymph are transported in man via the lymphatics by extrinsic forces such as muscle contractions, respiratory movements and *vis a tergo*.

We have found that rhythmic intrinsic contractility of subcutaneous lymphatics in the human leg generates pressure waves necessary to propel lymph. Studies were carried out in 12 randomly selected male volunteers. Leg subcutaneous lymph collecting vessels were cannulated against the direction of lymph flow and on day 2–5 after cannulation intravascular end pressures and the lymph flow rate were measured. Pressures were recorded in the upright and horizontal positions, while legs were kept motionless. Low pressure transducer AE 840 (Solid State Products) and Beckman R-611 Dynograph recorder were used. In all investigated subjects rhythmic pulse waves were noted with a frequency of 1–9 s, average 4 s, separated by periods of steady pressure lasting from 15–50 s. However, in some subjects, mostly after prolonged walking, continuous pulsation was observed. The time of each pulse wave was 6–8 s, but in most instances 6 s. The pulse pressures ranged from 1 to 40 mmHg. The highest pulse pressures were noted at low mean pressures (below 50 mmHg). At higher pressures the amplitude of pulse waves seemed to be dampened. Also at high pressures, the frequency of pulsation was higher than at low pressures, and often without relaxation periods. The highest observed intralymphatic end pressure was around 50 mmHg in 9 subjects, 90 mmHg in one and 120 mmHg in two. In 3 men the same rhythm of lymphatic pulse waves as that of the expression of drops of lymph from the end of the cannula was observed. In all cases pulse waves were completely asynchronous with arterial pulse rate, respiratory movements and movements of leg muscles.

The presented observations do not permit any analysis of the nature of the lymphatic pulse. They showed, however, that in human legs lymph can be driven by intrinsic contractions of the lymphatics. These findings may have bearing on the understanding of the transport of protein containing tissue fluid and lymph back to the blood circulation, as well as of oedema formation and of different pathologies of lymph vessels in man.

117. Inhibition of secretion produced by lesser curve myotomy in the dog

T. V. TAYLOR and I. F. ANSELL (Introduced by A. P. M. FORREST), *Department of Clinical Surgery, Edinburgh Royal Infirmary*

Branches of the nerve of Latarjet run with the serosa of the stomach before penetrating the muscularis (Mitchell, 1940). Myotomy of the pylorus and oesophagus are safe and well-established procedures. Myotomy of the lesser curve of the stomach with preservation of the major vessels should denervate the parietal cell mass. Four dogs with gastric cannulas had pentagastrin infusions (0·375–6 μg kg^{-1} h^{-1} i.v.) each on three separate occasions before and after lesser curve myotomy.

After myotomy in response to pentagastrin there was a shift to the right of acid secretion with a 33 per cent reduction in the peak, a finding similar to that reported after truncal vagotomy (Emas and Grossman, 1967). Total pepsin (Hunt, 1948) secretion was more markedly depressed by myotomy (77·7 per cent) than by truncal vagotomy. Myotomy abolished the secretory response to insulin in three dogs and in one there was a late positive response of small magnitude. Pepsin secretion did not rise above basal levels in response to insulin postoperatively.

Secretory inhibition after lesser curve myotomy is equal to that produced by vagotomy. This would appear to give the operation a sound anatomical and physiological basis, for technically it is easy to perform and obviates the risk of damage to the nerve of Latarjet or of ischaemic necrosis of the lesser curvature.

118. Technical and functional results after restorative resection of radiation damaged rectum

S. A. R. COOKE, *Department of Surgery, Medical School, Witwatersrand University, Johannesburg, South Africa*

Technical and functional results of resectional surgery for the rectal complications of radiation therapy are reported. Thirty-two consecutive patients underwent subtotal rectal resection with restoration of continuity by transanal colo-anal sleeve anastomosis. They comprised 26 patients with rectovaginal fistulas, 3 suffering severe haemorrhage, 2 with rectal strictures and 1 with radiation proctitis and carcinoma. Technical success was obtained in 30 of 32 patients. The amount of rectal muscle wall retained remained fairly constant; the length of mucosa preserved varied.

The ability to retain a water-soluble contrast enema was present in 83 per cent of 30 patients 3 months after surgery. Subjectively, total continence was present in 53 per cent at 3 months, 64 per cent at 6 months and 79 per cent at 1 year. Anastomosis at dentate line level resulted in total continence in 1 of 6, compared to all of 18 when 1–2 cm of mucosa above the dentate line was preserved, assessed 1 year after operation.

Anorectal manometry using open perfused tubes showed the maximum anal resting pressure (cmH_2O) to be significantly higher ($P<0·02$) where preservation of 1–2 cm of mucosa was possible (mean 40·15), compared to those whose anastomosis was at dentate line level (mean 22·83).

119. A mechanism for prostaglandin cytoprotection

J. M. MCGREEVY and F. G. MOODY, *Department of Surgery, University of Utah Medical Center, Salt Lake City, Utah, USA*

Does dimethyl prostaglandin of the E_2 series protect canine gastric secretory mucosa from aspirin-induced erosive gastritis through stimulation of a sodium-rich alkaline secretion? The mucosa of partitioned chambered segments of canine stomach ($n=9$) were exposed to 20 ml of isosmotic hydrochloric acid, or 20 μg of 16,16-dmPGE_2 or 20 mM of aspirin in isosmotic acid. Counterpressure (CP) of 40 mmHg was placed on the test (T) side of the partitioned chamber. Solutions recovered at 15 min intervals were analysed for changes in volume (V), sodium (Na) and hydrogen (H^+). Mucosal blood flow (MBF) was estimated by radioactive microspheres. Injury was determined by gross inspection and graded 0–5. The results are represented as the mean ± its standard error.

Two control and 6 test mucosas developed gross erosions. The mucosas exposed to counterpressure had more extensive injury (lesion index, control 0·8±0·3 *v.* test 2·0±0·6, $P<0·01$). Thus, the outflow of alkaline secretion which accompanies topical PGE and aspirin was lessened by counterpressure, and the protection offered by PGE compromised. Blood flow also decreased. These results suggest that prostaglandin cytoprotection from aspirin injury may be related in part to filtration of a sodium-rich alkaline secretion.

	HCl/No CP		PGE/No CP		PGE/CP

120. The effect of surgical operation upon phagocytosis by monocytes

N. W. EVERSON, R. STACEY, R. F. M. WOOD and P. R. F. BELL, *Department of Surgery, University of Leicester*

Increasing attention is being paid to the role of the mononuclear phagocytic system (MPS) in the immune process, particularly in relation to cancer and organ transplantation. Although the effect of surgical operation upon colloid clearance by the 'fixed' cells of the MPS, and upon the function of lymphocytes and granulocytes, has been studied, the circulating component of the MPS—the monocyte—has received little attention.

In this study, monocytes were isolated from the blood of patients undergoing surgery mainly for benign disease and the uptake by these cells of ^{99}Tc-labelled latex particles assessed using a modification of a previously described technique (Al-Ibrahim et al., 1976). Healthy volunteers served as controls. Lymphocytes and monocytes were separated from the blood, following which the monocytes were counted using a specific stain and allowed to adhere to glass coverslips. Results were expressed as the percentage uptake of a known added amount of ^{99}Tc latex.

The results (Table) show that a marked increase in phagocytosis occurs by 24 h following surgery ($P=0·01$), with a return towards normal values by 48 h. In another group of patients studied at 1 h postoperatively no change in monocyte function was observed, a finding which is in contrast to previous studies on the 'fixed' MPS reporting diminished function at this time.

Table: PERCENTAGE UPTAKE OF ^{99}Tc-LABELLED PARTICLES (mean±s.d.)

	No.	Preop.	1 h postop.	24 h postop.	48 h postop.
Patients	10	0·48		1·35*	0·55
		±0·44		±1·13	±0·49
	8	0·95	0·92		
		±0·27	±0·27		
Controls	10	0·33		0·35	0·24
		±0·25		±0·12	±0·075

* $P=0·01$ of Preop. (Wilcoxin signed rank test).

AL-IBRAHIM M. S., CHANDRA R., KISMORE R. et al. (1976) A micromethod for evaluating the phagocytic activity of human macrophages by ingestion of radio-labelled polystyrene particles. *J. Immunol. Method* **10**, 207–218.

121. Serum-mediated and cell-dependent post-thermal injury hypermetabolism

D. N. HERNDON, D. W. WILMORE, A. D. MASON JUN. and P. W. CURRERI, *Burn Center, Department of Surgery, Cornell Medical Center, New York City, USA*

Increased basal metabolic rate, protein catabolism and body weight loss characterize the metabolic response to major thermal injury in man and rats. The mediators and the organ system and cellular expression of the hypermetabolism are poorly understood. The post-thermal injury metabolic response of liver and white cells and the role of serum as an effector of these responses is evaluated by *in vitro* tissue slice and cell suspension oxygen consumption determinations following 50 per cent full-thickness scald burns in rats.

The oxygen consumption of 20 burned and 20 sham-burned 540-g rats was determined between days 10 and 15 post burn at ambient temperatures of 31±1·5 °C at 100 per cent humidity during 1½ h study periods in closed metabolic chambers. On the fifteenth day post burn the rats were sacrificed, 15 ml of heparinized blood obtained from each rat and plasma decanted. Purified leucocytes were prepared by treatment with ammonium chloride and differential centrifugation in Ficol-Hypaque to separate leucocytes from lymphocytes and monocytes. Livers were removed and 100-μg tissue slices were prepared with a Stadie Riggs microtome. Oxygen consumption of liver slices and white blood cell suspensions from burned and control rats were determined in aliquots of both burn and control serum with a Yellow Springs electrode oxygen metre at 37·5 °C equilibrated with 100 per cent oxygen. Determinations were corrected to standard temperature and pressure and expressed as $\mu l\ mg^{-1}\ h^{-1}$ for liver slices and $\mu l\ 10^{-6}$ cells h^{-1} for leucocytes. Statistical comparisons were made by four-way analysis of variance.

The burned rats prior to sacrifice were 45 per cent hypermetabolic relative to controls (burns oxygen consumption = 1·25±0·12, controls = 0·86±0·01 $ml\ g^{-1}\ h^{-1}$, $P<0{\cdot}001$). The metabolic rate of burn white blood cells is depressed to 43 per cent that of the controls ($P<0{\cdot}01$). This response was not serum-dependent. Burn and control livers were made 13–25 per cent hypermetabolic by incubation in burn serum ($P<0{\cdot}01$) but were not inherently different.

	Controls	
	C plasma	B plasma
Leucocytes	1·90±0·42	1·95±0·31
Liver slices	2·83±0·095	3·22±0·14

	Burns	
	C plasma	B plasma
Leucocytes	0·834±0·088	0·818±0·094
Liver slices	2·88 ±0·095	3·57 ±0·17

Oxygen consumption values = $\mu l\ 10^{-6}$ cells h^{-1} for leucocytes and $\mu l\ mg^{-1}\ h^{-1}$ for liver slices.

C, Control; B, burn.

In burned rats a plasma factor induces liver hypermetabolism, concomitant white blood cell hypometabolism is cell origin dependent. Definition of the plasma mediator may allow modulation of its hypermetabolic effects.

122. The effects of chronic volume overload on the diastolic mechanics of the left ventricle

W. S. RING, C. E. ARENTZEN, J. S. RANKIN, M. S. VISNER, R. J. BACHE and R. W. ANDERSON, *Department of Surgery, University of Minnesota, Minneapolis, Minnesota, USA*

Chronic volume overload (CVO) produces concentric left ventricular hypertrophy and dilatation associated with a shift to the right of the diastolic pressure-volume (PV) curve suggesting increased left ventricular (LV) compliance.

However, it is unclear whether this change in the diastolic filling properties results from altered intrinsic myocardial elastic properties (stress–strain relationship), or if it results simply from changes in ventricular geometry. To investigate this relationship chronic volume overload was produced in 6 adult mongrel dogs by creation of an 8-mm aortocaval shunt. In order to assess precisely dynamic LV geometry, dimension transducers were implanted 3–5 months later to measure minor and major axis diameters and equatorial wall thickness. LV transmural pressure was determined from measurements of left ventricular and pleural pressures. Pressure and dimension data were used to obtain the diastolic PV and stress–strain relationships and data from chronic volume overloaded animals were compared with data from normal (NL) dogs. The cardiac index was increased (8·4±0·9 $l\ min^{-1}\ m^{-2}$ in CVO *v.* 2·8±0·2 $l\ min^{-1}\ m^{-2}$ in NL). Normalized left ventricular mass was 6·2±1·1 g/kg body weight (NL = 3·9±0·2). The static diastolic PV curve in chronic volume overload was shifted to the right when compared with control animals indicating an increased diastolic LV chamber compliance. However, the diastolic myocardial elastic properties characterized by the diastolic stress–strain relationship remained entirely normal. These data indicate that the altered diastolic filling properties observed in compensated chronic volume overload result entirely from changes in ventricular geometry and not from changes in the material properties of the myocardium.

123. Liver tolerance to normothermic ischaemia: an experimental study in the pig

B. NORDLINGER, D. DOUVIN, L. JAVAUDIN, M. BOSCHAT and C. HUGUET, *Unité de Recherche d'Hépatologie, Inserm U9, Hôpital Saint Antoine-184, Rue du Faubourg Saint-Antoine, 75012 Paris, France*

The liver does not tolerate more than 15 min of normothermic ischaemia. This classic concept based on experimental data has recently been challenged by reports of good tolerance to one hour's normothermic ischaemia in dogs or pigs (portal triad occlusion and splanchnic vein decompression) and humans (portal triad occlusion). The present study intends first to elucidate these apparent discrepancies and secondly to determine the maximum safe period of hepatic normothermic ischaemia.

Twenty-nine pigs, divided in 5 groups, were submitted to complete liver inflow occlusion. Group 1, 8 pigs; portal triad clamping of 45 or 60 min. (In all other groups intestinal veins were decompressed through a splenojugular external bypass during portal triad occlusion.) Group 2, 8 pigs, 60 min; group 3, 5 pigs, 90 min; group 4, 5 pigs, 120 min; group 5, 3 pigs, 180 min. No liver refrigeration was used. Liver specimens were taken before ischaemia, 20 min and 1 month after revascularization.

All animals in groups 1 and 5 died; all animals in groups 2, 3 and 4 survived. Changes in prothrombin time and plasma transaminase levels were mild and transient:

	SGOT*	SGPT*	PT %
Before isch.			
60	37±8	45±8	88±6
90	33±4	47±7	89±7
120	43±2	49±5	69±7
30 min after revasc.			
60	43±8	392±8	32±7
90	38±3	286±57	42±7
120	73±28	1205±478	51±9
3rd day postop.			
60	70±5	82±5	97±3
90	52±7	57±16	95±2
120	84±32	93±30	74±4

60, 90, 120 = duration of ischaemia (min).
Isch, Ischaemia; revasc., revascularization.
PT, Prothrombin time.
Values are mean±1 s.d.
* Normal <40 μ/ml.

No substantial pathological changes were observed on early (20 min) or late (1 month and 3 months in one case) liver specimens.

We conclude that pigs tolerate 2 h hepatic normothermic ischaemia provided that splanchnic venous pooling is prevented. Since splanchnic venous distension is well tolerated in humans, one can thus understand why portal triad occlusion is safe far beyond 15 min in humans. The myth of the high sensitivity of the liver to warm ischaemia should be revised.

• •

124. Successful prolongation of canine pancreas allografts with cyclosporin A

A. PROCYSHYN, P. MCMASTER, R. Y. CALNE, R. VALDES and K. ROLLES, *Department of Surgery, Addenbrooke's Hospital, Cambridge*

Human pancreas allografts usually fail because of exocrine leakage and infection or because of pancreatic rejection. The prevention of pancreatic rejection by steroids is not ideal in an operation usually undertaken to improve carbohydrate control.

Cyclosporin A (CyA) is a non-steroid fungal metabolite which is an effective immunosuppressive agent in organ allografts in animals (Calne and White, 1977) and encouraging pilot studies with CyA have been reported in kidney allografts in man.

This study was undertaken to assess the effectiveness of CyA alone in delaying rejection of animals undergoing whole organ pancreas transplantation.

Forty-nine mongrel dogs were divided into 5 groups. Group 1 underwent total pancreatectomy alone. In the remaining groups total pancreatectomy was followed by whole organ pancreas allografts, placed orthotopically (18 animals) or heterotopically (26 animals) with pancreatic duct to ureter drainage. Group 2, no immunosuppressive treatment; group 3 received prednisolone 0·5 mg kg^{-1} d^{-1} and azothioprine 3 mg kg^{-1} d^{-1}. Group 4 received CyA 10 mg k^{-1} d^{-1} and group 5, CyA 25 mg kg^{-1} d^{-1}.

Technical complications with vascular thrombosis or pancreatitis occurred frequently and below are reported the results of animals surviving longer than 72 h.

Group	No.	Period of normoglycaemia (d)	Survival (median)
1	5	<1	13
2	3	4	20
3	7	9	23*
4	6	24	32
5	9	44	57**

Normoglycaemia = $<2\times$preop. blood sugar.
Mann–Whitney U test $*P = <0{\cdot}05$, $**P = <0{\cdot}01$.

CyA would appear on its own to prolong significantly the period of normoglycaemia after canine pancreas allografts.

125. A new method of non-invasive destruction of renal calculi by shock waves

W. BRENDEL, CH. CHAUSSY, B. FORSSMANN and E. SCHMIEDT, *Institute for Surgical Research and Department of Urology, University of Munich, Marchioninistr. 15, D-8000 München 70, West Germany*

Until now, the lithotriptic destruction of renal calculi was accomplished by direct administration of ultrasound or electrohydraulic energy which is conducted by a catheter. However, this method can only be employed in cases of calculi of the urinary bladder or of the lower part of the ureter. Concrements of the renal pelvis are inaccessible by this technique. Besides, catheterization of the ureter is unpleasant and not without side effects.

The technique to be reported here is especially designed for the treatment of calculi of the renal pelvis, making catheterization of the ureter unnecessary. It was developed in collaboration with the Dornier Company in Germany. The principle, which has been successfully tested already in animal experiments, is disintegration of the concrement by energetic shock waves. The shock waves are generated outside of the body by underwater discharge of a condenser with the sparking electrodes localized in one focus of an elliptic cavity and have an amplitude >1 kbar and duration <1 μs. The shock waves formed are reflected at the concrement which is positioned in the other focus of the ellipse. The renal calculus, like any material of density very different from the wave conducting medium, is exposed to powerful tear and compressive forces, resulting in abrupt disintegration into small pieces, or even into small grains. However, the technique of precise localization of the renal concrement within the abdomen and subsequent positioning into focus opposite to the discharge electrodes, proved to be a formidable problem. This difficulty could be solved by employment of a two-dimensional X-ray scan which intersects in the second focus of the ellipsoid. Prior to administration, an affected patient is subjected to several reciprocative movements and manoeuvres over the ellipsoid until the renal concrement is exactly in target (i.e. second focus). Subsequently, one or several spark discharges are triggered until the calculus has disintegrated. This can be controlled by an X-ray monitor.

Until now, the technique has been tested in 60 mongrel dogs, where during previous operations renal calculi of different magnitude and consistency obtained from humans had been implanted into the renal pelvis. In any case where the concrement could be correctly moved into target position, disintegration on exposure was accomplished which was followed by subsequent excretion via the urinary tract. Damage to surrounding tissues was never observed. Only if shock waves strike on matter of very different density relative to the medium, as for example air-containing lung tissue, rupturing of tissue may occur. On the other hand, passage of shock waves through tissue containing fluid does not cause any damage as demonstrated in many experiments with tissue culture, blood samples or small animals in total. Currently, the equipment initially developed for experimentation in dogs is being adapted for human purposes because in a great number of different animal studies no evidence was obtained that non-invasive concrement destruction by shock waves should not be used in man.

127. The nature of insulin resistance in sepsis

G. H. A. CLOWES JUN., C. A. SARAVIS, C. J. CHA, J. F. FLOWERS and D. NEWELL, *Sears Laboratory, Department of Surgery, Harvard Medical School, Boston, Mass., USA*

The role of 'insulin resistance' in the metabolic abnormalities of severe sepsis was studied by correlation of clinical observations and animal experiments.

Fourteen patients (none in shock) with peritonitis or abscesses who fasted for 8 h were compared with 9 normal people who fasted overnight. The uptake or release of substrates, metabolites and amino acids (AA) by peripheral tissues were measured by femoral A – V differences and leg blood flow (dye dilution) (*Table I*).

In sepsis both blood glucose and insulin are elevated. However, the metabolic defect does not lie in insulin binding, glucose transport, or glycogen synthesis. Rather, 'insulin resistance' appears to be an inability in muscle to induce PDH and to increase oxidation of glucose. Associated are accelerated proteolysis, consumption of branch chain AA, release of glucogenic AA and lactate.

Table I: LEG UPTAKE OR RELEASE AND ARTERIAL BLOOD CONCENTRATION (mean±s.d.)

	Normal ($n = 9$)	Septic ($n = 14$)	Septic/normal
Blood insulin (U/l)	21±5	38±8	180%
Glucose uptake (μmol/m^2/min)	18±2	122±31	670%
Lactate release (μmol/m^2/min)	−17±4	−42±7	247%
FFA uptake (μmol/m^2/min)	24±7	7±5	29%
Selected amino acids release:			
Alanine	−9±3	−42±4	455%
Leucine	−2±2	−9±2	451%
Tyrosine	−0·6±1	−3±1	481%

The incubated soleus muscles of 3-day fasted normal 70-g rats were compared with those of septic fasted animals 3 days after caecal ligation (*Table II*).

Table II: INCUBATED SOLEUS MUSCLE

	Normal	Septic	Septic/normal
Blood insulin (U/l)	15 ($n = 16$)	27 ($n = 21$)	180±10%
Insulin binding at 6 mol insulin conc. (fmol/mg muscle)	3·53 ($n = 52$)	3·95 ($n = 56$)	112±29%
C-14 Deoxyglucose uptake (pmol/mg muscle)	67 ($n = 18$)	110 ($n = 17$)	164±92%
C-14 Glycogen synthesis (μmol glucose converted to glycogen mg^{-1} h^{-1})	6·6 ($n = 19$)	10·6 ($n = 20$)	161±28%
C-14 Carbon dioxide production from 14C(U) glucose (nmol mg^{-1} h^{-1})	5·63 ($n = 12$)	6·19 ($n = 19$)	110±8%

128. Evidence of immunophagocytic potential within the central nervous system

J. P. PHILLIPS, O. EREMIN and R. Y. CALNE, *Departments of Surgery, Neurosurgery and Immunology, Addenbrooke's Hospital, Cambridge*

The primary biological function of normal glial tissue, which constitutes up to 60 per cent of the human brain, remains unclear. While the mesodermal microglia cell is an important scavenger cell within the CNS none of the other ectodermal glial constituents are known to be lymphoid in origin and the brain lacks both a lymphoid organ analogous to the lymph node and a conventional afferent and efferent lymphatic system.

We found an absence of T lymphocytes, as measured by E rosetting, in all suspensions of normal brain and in 9 of 10 suspensions of brain tumours we examined. In contrast, using ox red blood cell rosettes with various antisera, we consistently found Ig, Fc and C3 surface membrane receptors on a remarkably high percentage of normal glia and astrocytoma cells. These latter findings are new. Similar markers are normally confined to immunophagocytic cells of the lymphoid system and possibly tumour cells (Eremin et al., 1976). While a classic T lymphocytic cell mediated response can occur within the brain, subject to an adequate antigenic stimulus and possibly breach of the blood–brain barrier, our experiments confirm this is rare in tumours and point to an additional immunophagocytic potential or surveillance role for macroglia, as well as for microglia, within the central nervous system.

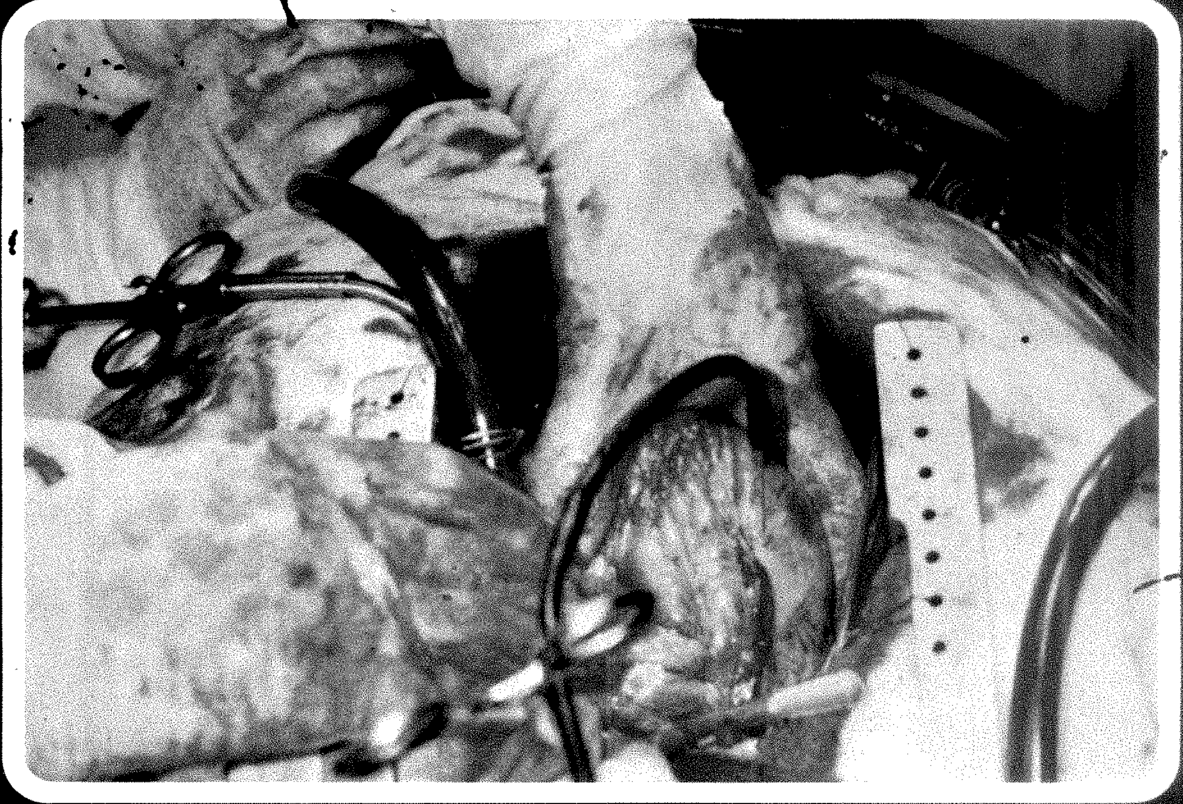
Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted 'Magnapen' containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as ucloxacillin sodium.

lagnapen Syrup: Bottles containing powder for the reparation of 100ml suspension. When reconstituted each ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. ith 125mg flucloxacillin as flucloxacillin sodium.

agnapen Vials: Each vial contains 250mg ampicillin as npicillin Sodium B.P. with 250mg flucloxacillin as cloxacillin sodium.

Severe infections. Post-operative chest and wound

Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial q.i.d. Children: 2-10 years ½ adult dose. Under 2 years ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL 0038/5001-5009

Contra-indications: Penicillin hypersensitivity. Ocular administration.

Side-effects: As with other penicillins. An erythematous rash may occasionally occur as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.

Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product

Basic N.H.S. Prices (correct at time of printing) [illegible]
Capsules 500mg £18.06 [illegible]
Syrup 250 mg per 5 ml £1.18 [illegible]
Vials 500mg £7.45 [illegible]

Magnapen is available [illegible] dependent upon estimated usage.

Further information on Magnapen is available [illegible] the company.

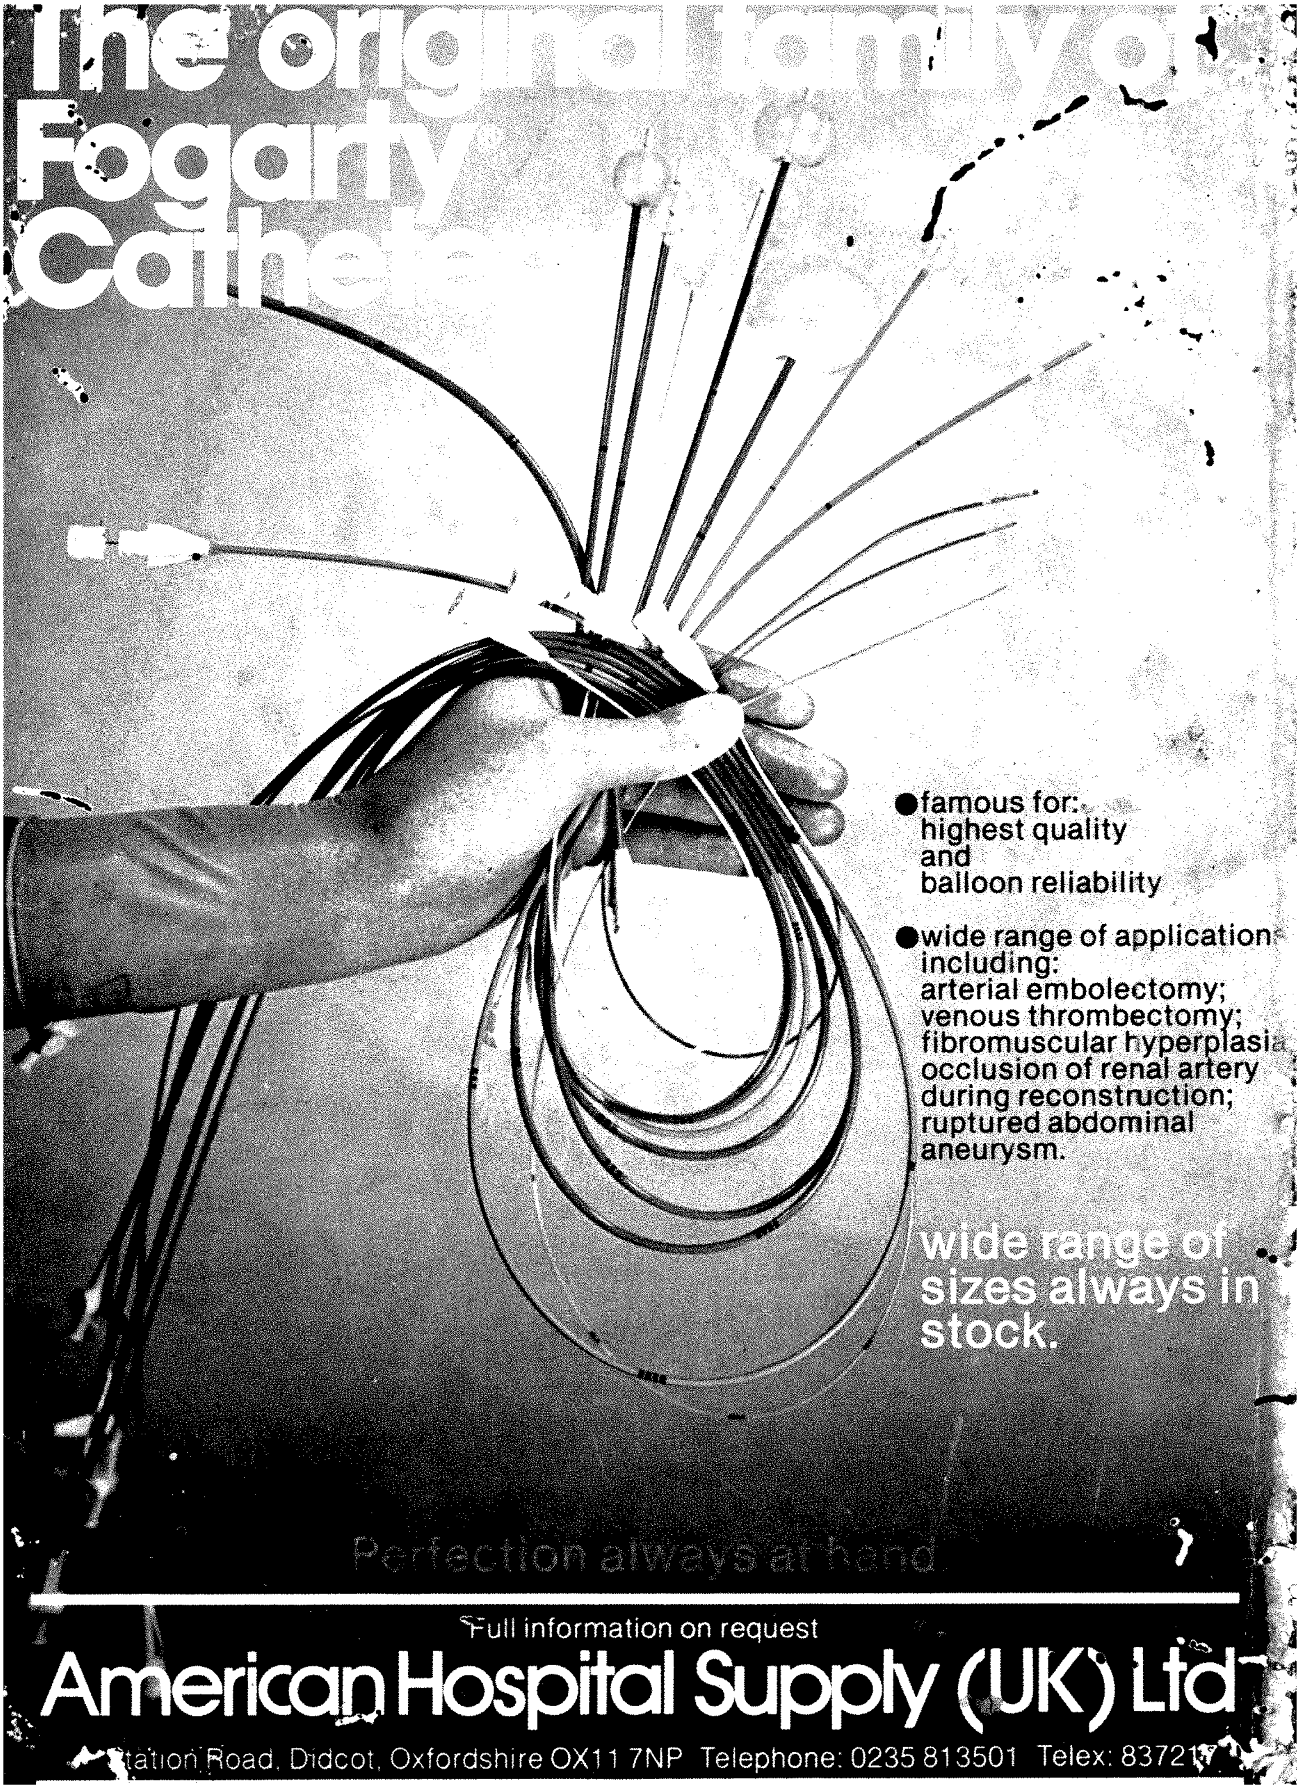
Beecham Research Laboratories
Brentford, England



The original family of Fogarty® Catheters

- famous for:
  highest quality
  and
  balloon reliability
- wide range of applications including:
  arterial embolectomy;
  venous thrombectomy;
  fibromuscular hyperplasia;
  occlusion of renal artery during reconstruction;
  ruptured abdominal aneurysm.

wide range of sizes always in stock.

Perfection always at hand.
